

ASYMPTOTIC REDUNDANCIES FOR UNIVERSAL QUANTUM CODING

CHRISTIAN KRATTENTHALER[†] AND PAUL B. SLATER

ABSTRACT. Clarke and Barron have recently shown that the Jeffreys' invariant prior of Bayesian theory yields the common asymptotic (minimax and maximin) redundancy of universal data compression in a parametric setting. We seek a possible analogue of this result for the two-level *quantum* systems. We restrict our considerations to prior probability distributions belonging to a certain one-parameter family, q_u , $-\infty < u < 1$. Within this setting, we are able to compute exact redundancy formulas, for which we find the asymptotic limits. We compare our quantum asymptotic redundancy formulas to those derived by naively applying the classical counterparts of Clarke and Barron, and find certain common features. Our results are based on formulas we obtain for the eigenvalues and eigenvectors of $2^n \times 2^n$ (Bayesian density) matrices, $\zeta_n(u)$. These matrices are the weighted averages (with respect to q_u) of all possible tensor products of n identical 2×2 density matrices, representing the two-level quantum systems. We propose a form of *universal* coding for the situation in which the density matrix describing an ensemble of quantum signal states is unknown. A sequence of n signals would be projected onto the dominant eigenspaces of $\zeta_n(u)$.

Index terms — quantum information theory, two-level quantum systems, universal data compression, asymptotic redundancy, Jeffreys' prior, Bayes redundancy, Schumacher compression, ballot paths, Dyck paths, relative entropy, Bayesian density matrices, quantum coding, Bayes codes, monotone metric, symmetric logarithmic derivative, Kubo-Mori/Bogoliubov metric

1. INTRODUCTION

In recent years, there have been a considerable number of important developments in the extension of (classical) information-theoretic concepts to a quantum-mechanical setting. Bennett and Shor [8] have surveyed this progress in the outstanding Commemorative Issue 1948–1998 of the *IEEE Transactions on Information Theory*. In particular, they pointed out — in strict analogy to the classical case, successfully studied some fifty years ago by Shannon in famous landmark work [48] — that quantum data compression allows signals from a redundant quantum source to be compressed into a bulk approaching the source's (quantum) entropy. Bennett and Shor did not, however, discuss the intriguing case which arises when the specific nature of the quantum source is *unknown*. This, of course, corresponds to the classical question of *universal* coding or data compression (see [20], [56, Sec. II.E]).

We do address this interesting issue here, by investigating whether or not it is possible to extend to the quantum domain, recent (classical) seminal results of Clarke and Barron [16, 17, 18]. They, in fact, derived various forms of asymptotic redundancy of universal

[†]Research supported in part by the MSRI, Berkeley

data compression for parameterized families of probability distributions. Their analyses provide a rigorous basis for the reference prior method in Bayesian statistical analysis. For an extensive commentary on the results of Clarke and Barron, see [45]. Also see [15], for some recent related research, as well as a discussion of various rationales that have been employed for using the (classical) Jeffreys' prior — a possible quantum counterpart of which will be of interest here — for Bayesian purposes, cf. [31]. Let us also bring to the attention of the reader that in a brief review [25] of [17], the noted statistician, I. J. Good, commented that Clarke and Barron “have presumably overlooked the reviewer's work” and cited, in this regard [26, 27].¹

Let us briefly recall the basic setup and the results of Clarke and Barron that are relevant to the analyses of our paper. Clarke and Barron work in a noninformative Bayesian framework, in which we are given a parametric family of probability densities $\{P_\theta : \theta \in \Theta \subseteq \mathbb{R}^d\}$ on a space X . These probability densities generate independent identically distributed random variables X_1, X_2, \dots, X_n , which, for a fixed θ , we consider as producing strings of length n according to the probability density P_θ^n of the n -fold product of probability distributions. Now suppose that Nature picks a θ from Θ , that is a joint density P_θ^n on the product space $X^n = (X_1, X_2, \dots, X_n)$, the space of strings of length n . On the other hand, a Statistician chooses a distribution Q_n on X^n as his best guess of P_θ^n . Of course, there is a loss of information, which is measured by the total relative entropy $D(P_\theta^n \| Q_n)$, where $D(P \| Q)$ is the *Kullback–Leibler divergence* of P and Q (the *relative entropy* of P with respect to Q). For finite n , and for a given prior $w(\theta)d\theta$ on Θ , by a result of Aitchison [2, pp. 549/550], the best strategy Q_n to minimize the average risk $\int D(P_\theta^n \| Q_n)w(\theta)d\theta$ is to choose for Q_n the mixture density $M_n^w = \int P_\theta^n w(\theta)d\theta$. This is called a *Bayes procedure* or a *Bayes strategy*.

The quantities corresponding to such a procedure that must be investigated are the *risk (redundancy) of the Bayes strategy* $D(P_\theta^n \| M_n^w)$ and the *Bayes risk*, the average of risks, $\int D(P_\theta^n \| M_n^w)w(\theta)d\theta$. The Bayes risk equals Shannon's mutual information $I(\Theta; X^n)$ (see [16, 20]). Moreover, the Bayes risk is bounded above by the *minimax redundancy* $\min_{Q_n} \max_{\theta \in \Theta} D(P_\theta^n \| Q_n)$. In fact, by a result of Gallager [23] and Davisson and Leon–Garcia [21] (see [28] for a generalization), for each fixed n there is a prior w_n^* which realizes this upper bound, i.e., the *maximin redundancy* $\max_w \int D(P_\theta^n \| M_n^w)w(\theta)d\theta$ and the minimax redundancy are the same. Such a prior w_n^* is called *capacity achieving* or *least favorable*.

Clarke and Barron investigate the above-mentioned quantities *asymptotically*, that is, for n tending to infinity. First of all, in [16, (1.4)], [17, (2.1b)], they show that the redundancy $D(P_\theta^n \| M_n^w)$ of the Bayes strategy is asymptotically

$$\frac{d}{2} \log \frac{n}{2\pi e} + \frac{1}{2} \log \det I(\theta) - \log w(\theta) + o(1), \quad (1.1)$$

as n tends to infinity. Here, $I(\theta)$ is the $d \times d$ Fisher information matrix — the negative of the expected value of the Hessian of the logarithm of the density function. (Although the binary logarithm is usually used in the quantum coding literature, we employ the

¹It should be noted that in these papers, Good uses a more general objective function — a two-parameter utility — than the relative entropy, chosen by Clarke and Barron over alternative measures [16, p. 454]. Good does conclude that Jeffreys' invariant prior is the minimax, that is, the least favorable, prior when the utility is the “weight of the evidence” in the sense of C. S. Pierce, that is, the relative entropy.

natural logarithm throughout this paper, chiefly to facilitate comparisons of our results with those of Clarke and Barron [16, 17, 18].) For priors supported on a compact subset K in the interior of the domain Θ of parameters, the asymptotic minimax redundancy $\min_{Q_n} \max_{\theta \in \Theta} D(P_\theta^n \| Q_n)$ was shown to be [17, (2.4)], [18],

$$\frac{d}{2} \log \frac{n}{2\pi e} + \log \int_K \sqrt{\det I(\theta)} d\theta + o(1). \quad (1.2)$$

Moreover [17, (2.6)], it is *Jeffreys' prior* $w^* = \sqrt{\det I(\theta)}/c$ (with $c = \int_K \sqrt{\det I(\theta)} d\theta$) a normalizing constant; see also [10]) which is the unique continuous and positive prior on K which is asymptotically least favorable, i.e., for which the asymptotic maximin redundancy achieves the value (1.2). In particular, asymptotically the maximin and minimax redundancies are the same.

In obvious contrast to classical information theory, quantum information theory directly relies upon the fundamental principles of quantum mechanics. This is due to the fact that the basic unit of quantum computing, the “quantum bit” or “qubit,” is typically a (two-state) microscopic system, possibly an atom or nuclear spin or polarized photon, the behavior of which (e.g. entanglement, interference, superposition, stochasticity, ...) can only be accurately explained using the rules of quantum theory [39]. We refer the reader to [8] for a comprehensive introduction to these matters (including the subjects of quantum error-correcting codes and quantum cryptography). Here, we shall restrict ourselves to describing, in mathematical terms, the basic notions of quantum information theory, how they pertain to data compression, and in what manner they parallel the corresponding notions from classical information theory.

In quantum information theory, the role of probability densities is played by *density matrices*, which are, by definition, nonnegative definite Hermitian matrices of unit trace, and which can be considered as operators acting on a (finite-dimensional) Hilbert space. Any probability density on a (finite) set $X = \{x_1, x_2, \dots, x_m\}$, where the probability of x_i equals p_i , is representable in this framework by a diagonal matrix $\text{diag}(p_1, p_2, \dots, p_m)$ (which is quite clearly itself, a nonnegative definite Hermitian matrix with unit trace). Given two density matrices ρ_1 and ρ_2 , the quantum counterpart of the relative entropy, that is, the *relative entropy* of ρ_1 with respect to ρ_2 , is [38, 59] (cf. [41]),

$$S(\rho_1, \rho_2) = \text{Tr } \rho_1 (\log \rho_1 - \log \rho_2), \quad (1.3)$$

where the logarithm of a matrix ρ is defined as $\sum_{k \geq 1} (-1)^{k-1} (\rho - I)^k / k$, with I the appropriate identity matrix. (Alternatively, if ρ acts diagonally on a basis $\{v_1, v_2, \dots, v_m\}$ of the Hilbert space by $\rho v_i = \lambda_i v_i$, then $\log \rho$ acts by $(\log \rho) v_i = (\log \lambda_i) v_i$, $i = 1, 2, \dots, m$.) Clearly, if ρ_1 and ρ_2 are diagonal matrices, corresponding to classical probability densities, then (1.3) reduces to the usual Kullback–Leibler divergence.

As we said earlier, our goal is to examine the possibility of extending the results of Clarke and Barron to quantum theory. That is, first of all we have to replace the (classical) probability densities P_θ by density matrices. We are not able to proceed in complete generality, but rather we will restrict ourselves to considering the first nontrivial case, that is, we will replace P_θ by 2×2 density matrices. Such matrices can be written in the form,

$$\rho = \frac{1}{2} \begin{pmatrix} 1+z & x-iy \\ x+iy & 1-z \end{pmatrix}, \quad (1.4)$$

where, in order to guarantee nonnegative definiteness, the points (x, y, z) must lie within the unit ball (“Bloch sphere” [12]), $x^2 + y^2 + z^2 \leq 1$. (The points on the bounding spherical surface, $x^2 + y^2 + z^2 = 1$, corresponding to the *pure states*, will be shown to exhibit nongeneric behavior, see (2.39) and the respective comments in Sec. 3 (cf. [22]).) Such 2×2 density matrices correspond, in a one-to-one fashion, to the standard (complex) two-level quantum systems — notably, those of spin-1/2 (electrons, protons, . . .) and massless spin-1 particles (photons). These systems carry the basic units of quantum computing, the *quantum bits*. (If we set $x = y = 0$ in (1.4), we recover a classical binomial distribution, with the probability of “success”, say, being $(1 + z)/2$ and of “failure”, $(1 - z)/2$. Setting either x or y to zero, puts us in the framework of real — as opposed to complex — quantum mechanics.)

The quantum analogue of the product of (classical) probability distributions is the *tensor product* of density matrices. (Again, it is easily seen that, for diagonal matrices, this reduces to the classical product.) Hence, we will replace P_θ^n by the tensor products $\otimes^n \rho$, where ρ is a 2×2 density matrix (1.4). These tensor products are $2^n \times 2^n$ matrices, and can be used to compute (*via* the fundamental rule that the expected value of an observable is the trace of the matrix product of the observable and the density matrix; see [39]) the probability of strings of quantum bits of length n .

In [50, 51] it was argued that the quantum Fisher information matrix (requiring — due to noncommutativity — the computation of symmetric logarithmic derivatives [42]²) for the density matrices (1.4) should be taken to be of the form

$$\frac{1}{(1 - x^2 - y^2 - z^2)} \begin{pmatrix} 1 - y^2 - z^2 & xy & xz \\ xy & 1 - x^2 - z^2 & yz \\ xz & yz & 1 - x^2 - y^2 \end{pmatrix}. \quad (1.5)$$

The quantum counterpart of the Jeffreys’ prior was, then, taken to be the normalized form (dividing by π^2) of the square root of the determinant of (1.5), that is,

$$(1 - x^2 - y^2 - z^2)^{-1/2} / \pi^2. \quad (1.6)$$

On the basis of the above-mentioned result of Clarke and Barron that the Jeffreys’ prior yields the asymptotic common minimax and maximin redundancy, it was conjectured [53] that its assumed quantum counterpart (1.6) would have similar properties, as well.

To examine this possibility, (1.6) was embedded as a specific member ($u = .5$) of a one-parameter family of spherically-symmetric/unitarily-invariant probability densities (i.e., under unitary transformations of ρ , the assigned probability is invariant),

$$q_u = q_u(x, y, z) := \frac{\Gamma(5/2 - u)}{\pi^{3/2} \Gamma(1 - u) (1 - x^2 - y^2 - z^2)^u}, \quad -\infty < u < 1. \quad (1.7)$$

²Following [22], in order to derive (1.5), one must find the symmetric logarithmic derivatives (L_x, L_y, L_z) satisfying

$$\frac{\partial \rho}{\partial \alpha} = (\rho L_\alpha + L_\alpha \rho) / 2, \quad \alpha = x, y, z,$$

and then compute the entries of (1.5) in the form [50, eqs. (2), (3)]

$$I_{\beta\gamma} = \text{Tr}[\rho(L_\beta L_\gamma + L_\gamma L_\beta) / 2], \quad \beta, \gamma = x, y, z.$$

For a well-motivated discussion of these formulas and the manner in which classical and quantum Fisher information are related, see [34].

(Embeddings of (1.6) in other (possibly, multiparameter) families are, of course, possible and may be pursued in further research. In this regard, see Theorem 11 in Sec. 3.) For $u = 0$, we obtain a uniform distribution over the unit ball. (This has been used as a prior over the two-level quantum systems, at least, in one study [32].) For $u \rightarrow 1$, the uniform distribution over the spherical boundary (the locus of the pure states) is approached. (This is often employed as a prior, for example [29, 32, 35].) For $u \rightarrow -\infty$, a Dirac distribution concentrated at the origin (corresponding to the fully mixed state) is approached.

For a treatment in our setting that is analogous to that of Clarke and Barron, we average $\bigotimes^n \rho$ with respect to q_u . Doing so yields a one-parameter family of $2^n \times 2^n$ *Bayesian density matrices* [18, 16, 36],

$$\zeta_n(u) = \int_{x^2+y^2+z^2 \leq 1} \left(\bigotimes^n \rho \right) q_u(x, y, z) dx dy dz,$$

$-\infty < u < 1$, which are the analogues of the mixtures M_n^w , and which exhibit highly interesting properties.

Now, still following Clarke and Barron, we have to compute the analogue of the risk $D(P_\theta^n \| M_n^w)$, i.e., the relative entropy $S(\bigotimes^n \rho, \zeta_n(u))$. Keeping the definition (1.3) in mind, this requires us to explicitly find the eigenvalues and eigenvectors of the matrices $\zeta_n(u)$, which we do in Sec. 2.2. Subsequently, in Sec. 2.3, we determine explicitly the relative entropy of $\bigotimes^n \rho$ with respect to $\zeta_n(u)$. We do this by using identities for hypergeometric series and some combinatorics. (It is also possible to obtain some of our results by making use of representation theory of $SU(2)$. An even more general result was derived by combining these two approaches. We comment on this issue at the end of Sec. 3.)

On the basis of these results, we then address the question of finding asymptotic estimations in Sec. 2.4 and 2.5. These, in turn, form the basis of examining to what degree the results of Clarke and Barron are capable of extension to the quantum domain.

Let us (naively) attempt to apply the formulas of Clarke and Barron [17, 18] — (1.1) and (1.2) above — to the quantum context under investigation here. We do this by setting d to 3 (the dimensionality of the unit ball — which we take as K), $\det I(\theta)$ to $(1 - x^2 - y^2 - z^2)^{-1}$ (the determinant of the quantum Fisher information matrix (1.5)), so that $\int_K \sqrt{\det I(\theta)} d\theta$ is π^2 , and $w(\theta)$ to $q_u(x, y, z)$. Then, we obtain from the expression for the asymptotic redundancy (1.1),

$$\frac{3}{2}(\log n - \log 2 - 1) - \left(\frac{1}{2} - u \right) \log(1 - r^2) + \log \Gamma(1 - u) - \log \Gamma\left(\frac{5}{2} - u\right) + o(1), \quad (1.8)$$

where $r = \sqrt{x^2 + y^2 + z^2}$, and from the expression for the asymptotic minimax redundancy (1.2),

$$\frac{3}{2}(\log n - \log 2 - 1) + \frac{1}{2} \log \pi + o(1). \quad (1.9)$$

We shall (in Sec. 3) compare these two formulas, (1.8) and (1.9), with the results of Sec. 2 and find some striking similarities and coincidences, particularly associated with the fully mixed state ($r = 0$). These findings will help to support the working hypothesis of this study — that there are meaningful extensions to the quantum domain of the

(commutative probabilistic) theorems of Clarke and Barron. However, we find that the minimax and maximin properties of the Jeffreys' prior do not strictly carry over, but transfer only in an approximate sense, which is, nevertheless, still quite remarkable. In any case, we can not formally rule out the possibility that the actual global (perhaps common) minimax and maximin are achieved for probability distributions not belonging to the one-parameter family q_u .

In analogy to [17, Sec. 5.2], the matrices $\zeta_n(u)$ should prove useful for the *universal* version of Schumacher data compression [7, 19, 30, 47]. Schumacher's result [47, 30] must be considered as the quantum analogue of Shannon's noiseless coding theorem (see e.g. [60, Sec. 5.6]). Roughly, *quantum data compression*, as proposed by Schumacher [47], works as follows: A (quantum) signal source ("sender") generates signal states of a quantum system M , the ensemble of possible signals being described by a density operator ψ . The signals are projected down to a "dominant" subspace of M , the rest is discarded. The information in this dominant subspace is transmitted through a (quantum) channel. The receiver tries to reconstruct the original signal by replacing the discarded information by some "typical" state. The quality (or *faithfulness*) of a coding scheme is measured by the *fidelity*, which is by definition the overall probability that a signal from the signal ensemble M that is transmitted to the receiver passes a validation test comparing it to its original (see [47, Sec. IV]). What Schumacher shows is that, for each $\varepsilon > 0$ and $\delta > 0$, under the above coding scheme a compression rate of $S(\psi) + \delta$ qubits per signal is possible, where $S(\psi)$ is the *von Neumann entropy* of ψ ,

$$S(\psi) = -\text{Tr } \psi \log \psi, \quad (1.10)$$

at a fidelity of at least $1 - 2\varepsilon$. (Thus, the von Neumann entropy is the quantum analogue of the Shannon entropy, which features in Shannon's classical noiseless coding theorem. Indeed, as is easy to see, for diagonal matrices, corresponding to classical probability densities, the right-hand side of (1.10) reduces to the Shannon entropy.) This is achieved by choosing as the dominant subspace that subspace of the quantum system M which is the span of the eigenvectors of ψ corresponding to the largest eigenvalues, with the property that the eigenvalues add up to at least $1 - \varepsilon$.

Consequently, in a universal compression scheme, we propose to project blocks of n signals (qubits) onto those "typical" subspaces of 2^n -dimensional Hilbert space corresponding to as many of the dominant eigenvalues of $\zeta_n(u)$ as it takes to exceed a sum $1 - \varepsilon$. For all u , the leading one of the $\lfloor \frac{n}{2} \rfloor + 1$ distinct eigenvalues has multiplicity $n + 1$, and belongs to the $(n + 1)$ -dimensional (Bose–Einstein) symmetric subspace [3]. (Projection onto the symmetric subspace has been proposed as a method for stabilizing quantum computations, including quantum state storage [4].) For $u = 1/2$, the leading eigenvalue can be obtained by dividing the $(n + 1)$ -st Catalan number — that is, $\frac{1}{n+2} \binom{2(n+1)}{n+1}$ — by 4^n . (The Catalan numbers "are probably the most frequently occurring combinatorial numbers after the binomial coefficients" [54].)

Let us point out to the reader the quite recent important work of Petz and Sudár [42]. They demonstrated that in the quantum case — in contrast to the classical situation in which there is, as originally shown by Chentsov [14], essentially only one monotone metric and, therefore, essentially only one form of the Fisher information — there exists an infinitude of such metrics. "The monotonicity of the Riemannian metric g is crucial when one likes to imitate the geometrical approach of [Chentsov]. An infinitesimal statistical distance has to be monotone under stochastic mappings. We

note that the monotonicity of g is a strengthening of the concavity of the von Neumann entropy. Indeed, positive definiteness of g is equivalent to the strict concavity of the von Neumann entropy . . . and monotonicity is much more than positivity” [40].

The monotone metrics on the space of density matrices are given [42] by the operator monotone functions $f(t) : \mathbb{R}^+ \rightarrow \mathbb{R}^+$, such that $f(1) = 1$ and $f(t) = tf(1/t)$. For the choice $f = (1 + t)/2$, one obtains the minimal metric (of the symmetric logarithmic derivative), which serves as the basis of our analysis here. “In accordance with the work of Braunstein and Caves, this seems to be the canonical metric of parameter estimation theory. However, expectation values of certain relevant observables are known to lead to statistical inference theory provided by the maximum entropy principle or the minimum relative entropy principle when *a priori* information on the state is available. The best prediction is a kind of generalized Gibbs state. On the manifold of those states, the differentiation of the entropy functional yields the Kubo-Mori/Bogoliubov metric, which is different from the metric of the symmetric logarithmic derivative. Therefore, more than one privileged metric shows up in quantum mechanics. The exact clarification of this point requires and is worth further studies” [42]. It remains a possibility, then, that a monotone metric other than the minimal one (which corresponds to $q_{0.5}$, that is (1.6)) may yield a common global asymptotic minimax and maximin redundancy, thus, fully paralleling the classical/nonquantum results of Clarke and Barron [16, 17, 18]. We intend to investigate such a possibility, in particular, for the Kubo-Mori/Bogoliubov metric [40, 42, 43].

2. ANALYSIS OF A ONE-PARAMETER FAMILY OF BAYESIAN DENSITY MATRICES

In this section, we implement the analytical approach described in the Introduction to extending the work of Clarke and Barron [17, 18] to the realm of quantum mechanics, specifically, the two-level systems. Such systems are representable by density matrices ρ of the form (1.4). A composite system of n independent (unentangled) and identical two-level quantum systems is, then, represented by the n -fold tensor product $\bigotimes^n \rho$. In Theorem 1 of Sec. 2.1, we average $\bigotimes^n \rho$ with respect to the one-parameter family of probability densities q_u defined in (1.7), obtaining the Bayesian density matrices $\zeta_n(u)$ and formulas for their 2^{2n} entries. Then, in Theorem 2 of Sec. 2.2, we are able to explicitly determine the 2^n eigenvalues and eigenvectors of $\zeta_n(u)$. Using these results, in Sec. 2.3, we compute the relative entropy of $\bigotimes^n \rho$ with respect to $\zeta_n(u)$. Then, in Sec. 2.4, we obtain the asymptotics of this relative entropy for $n \rightarrow \infty$. In Sec. 2.5, we compute the asymptotics of the von Neumann entropy (see (1.10)) of $\zeta_n(u)$. All these results will enable us, in Sec. 3, to ascertain to what extent the results of Clarke and Barron could be said to carry over to the quantum domain.

2.1. Entries of the Bayesian density matrices $\zeta_n(u)$. The n -fold tensor product $\bigotimes^n \rho$ is a $2^n \times 2^n$ matrix. To refer to specific rows and columns of $\bigotimes^n \rho$, we index them by subsets of the n -element set $\{1, 2, \dots, n\}$. We choose to employ this notation instead of the more familiar use of binary strings, in order to have a more succinct way of writing our formulas. For convenience, we will subsequently write $[n]$ for $\{1, 2, \dots, n\}$. Thus,

$\bigotimes^n \rho$ can be written in the form

$$\bigotimes^n \rho = (R_{IJ})_{I, J \in [n]},$$

where

$$R_{IJ} = \frac{1}{2^n} (1+z)^{n_{\in \in}} (1-z)^{n_{\notin \notin}} (x+iy)^{n_{\notin \in}} (x-iy)^{n_{\in \notin}}, \quad (2.1)$$

with $n_{\in \in}$ denoting the number of elements of $[n]$ contained in both I and J , $n_{\notin \notin}$ denoting the number of elements *not* in both I and J , $n_{\notin \in}$ denoting the number of elements not in I but in J , and $n_{\in \notin}$ denoting the number of elements in I but not in J . In symbols,

$$\begin{aligned} n_{\in \in} &= |I \cap J|, \\ n_{\notin \notin} &= |[n] \setminus (I \cup J)|, \\ n_{\notin \in} &= |J \setminus I|, \\ n_{\in \notin} &= |I \setminus J|. \end{aligned}$$

We consider the average $\zeta_n(u)$ of $\bigotimes^n \rho$ with respect to the probability density $q_u = q_u(x, y, z)$ defined in (1.7) taken over the unit sphere $\{(x, y, z) : x^2 + y^2 + z^2 \leq 1\}$. This average can be described explicitly as follows.

Theorem 1. *The average $\zeta_n(u)$,*

$$\int_{x^2+y^2+z^2 \leq 1} \left(\bigotimes^n \rho \right) q_u(x, y, z) dx dy dz,$$

equals the matrix $(Z_{IJ})_{I, J \in [n]}$, where

$$\begin{aligned} Z_{IJ} &= \delta_{n_{\notin \in}, n_{\in \notin}} \left(\frac{n - n_{\in \in} - n_{\notin \notin}}{2} \right)! \\ &\times \frac{1}{2^n} \frac{\Gamma\left(\frac{5}{2} - u\right) \Gamma\left(2 + \frac{n}{2} + \frac{n_{\in \in}}{2} - \frac{n_{\notin \notin}}{2} - u\right) \Gamma\left(2 + \frac{n}{2} + \frac{n_{\notin \in}}{2} - \frac{n_{\in \notin}}{2} - u\right)}{\Gamma\left(\frac{5}{2} + \frac{n}{2} - u\right) \Gamma\left(2 + \frac{n}{2} - u\right) \Gamma\left(2 + \frac{n}{2} - \frac{n_{\in \in}}{2} - \frac{n_{\notin \notin}}{2} - u\right)}. \end{aligned} \quad (2.2)$$

Here, $\delta_{i,j}$ denotes the Kronecker delta, $\delta_{i,j} = 1$ if $i = j$ and $\delta_{i,j} = 0$ otherwise.

Remark. It is important for later considerations to observe that because of the term $\delta_{n_{\notin \in}, n_{\in \notin}}$ in (2.2) the entry Z_{IJ} is nonzero if and only if the sets I and J have the same cardinality. If I and J have the same cardinality, c say, then Z_{IJ} only depends on $n_{\in \in}$, the number of common elements of I and J , since in this case $n_{\notin \notin}$ is expressible as $n - 2c + n_{\in \in}$.

PROOF OF THEOREM 1. To compute Z_{IJ} , we have to compute the integral

$$\int_{x^2+y^2+z^2 \leq 1} R_{IJ} q_u(x, y, z) dx dy dz. \quad (2.3)$$

For convenience, we treat the case that $n_{\in \in} \geq n_{\notin \notin}$ and $n_{\notin \in} \geq n_{\in \notin}$. The other four cases are treated similarly.

First, we rewrite the matrix entries R_{IJ} ,

$$\begin{aligned}
& \frac{1}{2^n} (1+z)^{n_{\in \in}} (1-z)^{n_{\notin \in}} (x+iy)^{n_{\in \notin}} (x-iy)^{n_{\notin \in}} \\
&= \frac{1}{2^n} (1-z^2)^{n_{\in \in}} (1-z)^{n_{\notin \in} - n_{\in \in}} (x^2+y^2)^{n_{\in \notin}} (x-iy)^{n_{\in \notin} - n_{\notin \in}} \\
&= \frac{1}{2^n} \sum_{j,k,l \geq 0} (-1)^{j+k} (-i)^l \binom{n_{\in \in}}{j} \binom{n_{\notin \in} - n_{\in \in}}{k} \binom{n_{\in \notin} - n_{\notin \in}}{l} \\
&\quad \cdot z^{2j+k} (x^2+y^2)^{n_{\in \notin}} x^{n_{\in \notin} - n_{\notin \in} - l} y^l. \tag{2.4}
\end{aligned}$$

Of course, in order to compute the integral (2.3), we transform the Cartesian coordinates into polar coordinates,

$$\begin{aligned}
x &= r \sin \vartheta \cos \varphi \\
y &= r \sin \vartheta \sin \varphi \\
z &= r \cos \vartheta, \\
0 &\leq \varphi \leq 2\pi, \quad 0 \leq \vartheta \leq \pi.
\end{aligned}$$

Thus, using (2.4), the integral (2.3) is transformed into

$$\begin{aligned}
& \frac{1}{2^n} \sum_{j,k,l \geq 0} \int_0^1 \int_0^\pi \int_0^{2\pi} (-1)^{j+k} (-i)^l \binom{n_{\in \in}}{j} \binom{n_{\notin \in} - n_{\in \in}}{k} \binom{n_{\in \notin} - n_{\notin \in}}{l} \\
&\quad \cdot r^{2j+k+n_{\in \notin}+n_{\in \in}+2} (\cos^{2j+k} \vartheta) (\sin^{n_{\in \notin}+n_{\in \in}+1} \vartheta) \\
&\quad \cdot (\cos^{n_{\in \notin}-n_{\notin \in}-l} \varphi) (\sin^l \varphi) \frac{\Gamma(5/2-u)}{\pi^{3/2} \Gamma(1-u) (1-r^2)^u} d\varphi d\vartheta dr. \tag{2.5}
\end{aligned}$$

To evaluate this triple integral we use the following standard formulas:

$$\int_0^\pi \sin^{2M} \vartheta \cos^{2N} \vartheta d\vartheta = \pi \frac{(2M-1)!! (2N-1)!!}{(2M+2N)!!}, \tag{2.6a}$$

$$\int_0^\pi \sin^{2M+1} \vartheta \cos^{2N} \vartheta d\vartheta = 2 \frac{(2M)!! (2N-1)!!}{(2M+2N+1)!!} \tag{2.6b}$$

$$\text{and} \quad \int_0^{2\pi} \sin^{2M+1} \vartheta \cos^{2N} \vartheta d\vartheta = 0, \tag{2.6c}$$

$$\int_0^\pi \sin^{2M} \vartheta \cos^{2N+1} \vartheta d\vartheta = 0, \tag{2.6d}$$

$$\int_0^\pi \sin^{2M+1} \vartheta \cos^{2N+1} \vartheta d\vartheta = 0, \tag{2.6e}$$

for any nonnegative integers M and N . Furthermore, we need the beta integral

$$\int_0^1 \frac{r^m}{(1-r^2)^u} dr = \frac{\Gamma\left(\frac{m+1}{2}\right) \Gamma(1-u)}{2 \Gamma\left(\frac{m+3}{2} - u\right)}. \tag{2.7}$$

Now we consider the integral over φ in (2.5). Using (2.6c) and (2.6d), we see that each summand in (2.5) vanishes if $n_{\notin \in}$ has a parity different from $n_{\in \notin}$. On the other hand, if $n_{\notin \in}$ has the same parity as $n_{\in \notin}$, then we can evaluate the integrals over φ using

(2.6a) and (2.6e). Discarding for a moment the terms independent of φ and l , we have

$$\begin{aligned}
& \sum_{l \geq 0} \int_0^{2\pi} (-i)^l \binom{n_{\notin \in} - n_{\notin \in}}{l} (\cos^{n_{\notin \in} - n_{\notin \in} - l} \varphi) (\sin^l \varphi) d\varphi \\
&= \sum_{l \geq 0} (-1)^l \binom{n_{\notin \in} - n_{\notin \in}}{2l} 2\pi \frac{(2l-1)!! (n_{\notin \in} - n_{\notin \in} - 2l - 1)!!}{(n_{\notin \in} - n_{\notin \in})!!} \\
&= 2\pi \frac{(n_{\notin \in} - n_{\notin \in} - 1)!!}{(n_{\notin \in} - n_{\notin \in})!!} \sum_{l \geq 0} \binom{(n_{\notin \in} - n_{\notin \in})/2}{l} (-1)^l \\
&= 2\pi \delta_{n_{\notin \in}, n_{\notin \in}},
\end{aligned}$$

the last line being due to the binomial theorem. These considerations reduce (2.5) to

$$\begin{aligned}
& \delta_{n_{\notin \in}, n_{\notin \in}} \frac{1}{2^n} \sum_{j, k \geq 0} \int_0^1 \int_0^\pi (-1)^{j+k} \binom{n_{\in \in}}{j} \binom{n_{\notin \in} - n_{\in \in}}{k} \\
& \quad \cdot r^{2j+k+2n_{\notin \in}+2} (\cos^{2j+k} \vartheta) (\sin^{2n_{\notin \in}+1} \vartheta) \frac{2\Gamma(5/2-u)}{\pi^{1/2} \Gamma(1-u) (1-r^2)^u} d\vartheta dr.
\end{aligned}$$

Using (2.6c), (2.6e) and (2.7) this can be further simplified to

$$\begin{aligned}
& \delta_{n_{\notin \in}, n_{\notin \in}} \frac{1}{2^n} \sum_{j, k \geq 0} (-1)^j \binom{n_{\in \in}}{j} \binom{n_{\notin \in} - n_{\in \in}}{2k} \frac{2(2j+2k-1)!! (2n_{\notin \in})!!}{(2j+2k+2n_{\notin \in}+1)!!} \\
& \quad \cdot \frac{\Gamma(j+k+n_{\notin \in}+3/2) \Gamma(1-u)}{2\Gamma(j+k+n_{\notin \in}+5/2-u)} \frac{2\Gamma(5/2-u)}{\pi^{1/2} \Gamma(1-u)}. \quad (2.8)
\end{aligned}$$

Next we interchange sums over j and k and write the sum over k in terms of the standard hypergeometric notation

$${}_rF_s \left[\begin{matrix} a_1, \dots, a_r \\ b_1, \dots, b_s \end{matrix}; z \right] = \sum_{k=0}^{\infty} \frac{(a_1)_k \cdots (a_r)_k}{k! (b_1)_k \cdots (b_s)_k} z^k,$$

where the shifted factorial $(a)_k$ is given by $(a)_k := a(a+1) \cdots (a+k-1)$, $k \geq 1$, $(a)_0 := 1$. Thus we can write (2.8) in the form

$$\begin{aligned}
& \delta_{n_{\notin \in}, n_{\notin \in}} \frac{1}{2^n} \sum_{k \geq 0} \binom{n_{\notin \in} - n_{\in \in}}{2k} \frac{(2k-1)!! n_{\notin \in}! \Gamma(\frac{5}{2} - u)}{2^{k+1} \Gamma(\frac{5}{2} + k + n_{\notin \in} - u)} \\
& \quad \cdot {}_2F_1 \left[\begin{matrix} \frac{1}{2} + k, -n_{\in \in} \\ \frac{5}{2} + k + n_{\notin \in} - u \end{matrix}; 1 \right]. \quad (2.9)
\end{aligned}$$

The ${}_2F_1$ series can be summed by means of Gauß' ${}_2F_1$ summation (see e.g. [49, (1.7.6); Appendix (III.3)])

$${}_2F_1 \left[\begin{matrix} a, b \\ c \end{matrix}; 1 \right] = \frac{\Gamma(c) \Gamma(c-a-b)}{\Gamma(c-a) \Gamma(c-b)}, \quad (2.10)$$

provided the series terminates or $\operatorname{Re}(c-a-b) \geq 0$. Applying (2.10) to the ${}_2F_1$ in (2.9) (observe that it is terminating) and writing the sum over k as a hypergeometric series,

the expression (2.9) becomes

$$\delta_{n_{\in \notin}, n_{\notin \in}} \frac{1}{2^n} \frac{\Gamma(2 + n_{\in \in} + n_{\notin \in} - u) \Gamma\left(\frac{5}{2} - u\right) n_{\notin \in}!}{\Gamma\left(\frac{5}{2} + n_{\in \in} + n_{\notin \in} - u\right) \Gamma(2 + n_{\notin \in} - u)} \times {}_2F_1\left[\begin{matrix} \frac{n_{\in \in}}{2} - \frac{n_{\notin \notin}}{2}, \frac{1}{2} + \frac{n_{\in \in}}{2} - \frac{n_{\notin \notin}}{2} \\ \frac{5}{2} + n_{\in \in} + n_{\notin \in} - u \end{matrix}; 1\right].$$

Another application of (2.10) gives

$$\delta_{n_{\in \notin}, n_{\notin \in}} \frac{1}{2^n} \times \frac{\Gamma(2 + n_{\in \in} + n_{\notin \in} - u) \Gamma(2 + n_{\notin \notin} + n_{\notin \in} - u) \Gamma\left(\frac{5}{2} - u\right) n_{\notin \in}!}{\Gamma\left(\frac{5}{2} + \frac{n_{\in \in}}{2} + \frac{n_{\notin \notin}}{2} + n_{\notin \in} - u\right) \Gamma\left(2 + \frac{n_{\in \in}}{2} + \frac{n_{\notin \notin}}{2} + n_{\notin \in} - u\right) \Gamma(2 + n_{\notin \in} - u)}. \quad (2.11)$$

Trivially, we have $n = n_{\in \in} + n_{\notin \notin} + n_{\notin \in} + n_{\in \notin}$. Since (2.11) vanishes unless $n_{\notin \in} = n_{\in \notin}$, we can substitute $(n - n_{\in \in} - n_{\notin \notin})/2$ for $n_{\notin \in}$ in the arguments of the gamma functions. Thus, we see that (2.11) equals (2.2). This completes the proof of the Theorem. \square

2.2. Eigenvalues and eigenvectors of the Bayesian density matrices $\zeta_n(u)$.

With the explicit description of the result $\zeta_n(u)$ of averaging $\overset{n}{\otimes} \rho$ with respect to q_u at our disposal, we now proceed to describe the eigenvalues and eigenspaces of $\zeta_n(u)$. The eigenvalues are given in Theorem 2. Lemma 4 gives a complete set of eigenvectors of $\zeta_n(u)$. The reader should note that, though complete, this is simply a set of linearly independent eigenvectors and not a fully orthogonal set.

Theorem 2. *The eigenvalues of the $2^n \times 2^n$ matrix $\zeta_n(u)$, the entries of which are given by (2.2), are*

$$\lambda_h = \frac{1}{2^n} \frac{\Gamma\left(\frac{5}{2} - u\right) \Gamma(2 + n - h - u) \Gamma(1 + h - u)}{\Gamma\left(\frac{5}{2} + \frac{n}{2} - u\right) \Gamma(2 + \frac{n}{2} - u) \Gamma(1 - u)}, \quad h = 0, 1, \dots, \left\lfloor \frac{n}{2} \right\rfloor, \quad (2.12)$$

with respective multiplicities

$$\frac{(n - 2h + 1)^2}{(n + 1)} \binom{n + 1}{h}. \quad (2.13)$$

The Theorem will follow from a sequence of Lemmas. We state the Lemmas first, then prove Theorem 2 assuming the truth of the Lemmas, and after that provide proofs of the Lemmas.

In the first Lemma some eigenvectors of the matrix $\zeta_n(u)$ are described. Clearly, since $\zeta_n(u)$ is a $2^n \times 2^n$ matrix, the eigenvectors are in 2^n -dimensional space. As we did previously, we index coordinates by subsets of $[n]$, so that a generic vector is $(x_S)_{S \in [n]}$. In particular, given a subset T of $[n]$, the symbol e_T denotes the standard unit vector with a 1 in the T -th coordinate and 0 elsewhere, i.e., $e_T = (\delta_{S,T})_{S \in [n]}$.

Now let h, s be integers with $0 \leq h \leq s \leq n - h$ and let A and B be two disjoint h -element subsets A and B of $[n]$. Then we define the vector $v_{h,s}(A, B)$ by

$$v_{h,s}(A, B) := \sum_{\substack{X \subseteq A \\ Y \subseteq [n] \setminus (A \cup B), |Y| = s - h}} (-1)^{|X|} e_{X \cup X' \cup Y}, \quad (2.14)$$

where X' is the “complement of X in B ” by which we mean that if X consists of the i_1 -, i_2 -, \dots -largest elements of A , $i_1 < i_2 < \dots$, then X' consists of all elements of B *except for* the i_1 -, i_2 -, \dots -largest elements of B . For example, let $n = 7$. Then the vector $v_{2,3}(\{1, 3\}, \{2, 5\})$ is given by

$$\begin{aligned} e_{\{2,4,5\}} + e_{\{2,5,6\}} + e_{\{2,5,7\}} - e_{\{1,4,5\}} - e_{\{1,5,6\}} - e_{\{1,5,7\}} \\ - e_{\{2,3,4\}} - e_{\{2,3,6\}} - e_{\{2,3,7\}} + e_{\{1,3,4\}} + e_{\{1,3,6\}} + e_{\{1,3,7\}}. \end{aligned} \quad (2.15)$$

(In this special case, the possible subsets X of $A = \{1, 3\}$ in the sum in (2.14) are \emptyset , $\{1\}$, $\{3\}$, $\{1, 3\}$, with corresponding complements in $B = \{2, 5\}$ being $\{2, 5\}$, $\{5\}$, $\{2\}$, \emptyset , respectively, and the possible sets Y are $\{4\}$, $\{6\}$, $\{7\}$.) Observe that all sets $X \cup X' \cup Y$ which occur as indices in (2.14) have the same cardinality s .

Lemma 3. *Let h, s be integers with $0 \leq h \leq s \leq n - h$ and let A and B be disjoint h -element subsets of $[n]$. Then $v_{h,s}(A, B)$ as defined in (2.14) is an eigenvector of the matrix $\zeta_n(u)$, the entries of which are given by (2.2), for the eigenvalue λ_h , where λ_h is given by (2.12).*

We want to show that the multiplicity of λ_h equals the expression in (2.13). Of course, Lemma 3 gives many more eigenvectors for λ_h . Therefore, in order to describe a basis for the corresponding eigenspace, we have to restrict the collection of vectors in Lemma 3.

We do this in the following way. Fix h , $0 \leq h \leq \lfloor n/2 \rfloor$. Let P be a lattice path in the plane integer lattice \mathbb{Z}^2 , starting in $(0, 0)$, consisting of $n - h$ up-steps $(1, 1)$ and h down-steps $(1, -1)$, which never goes below the x -axis. Figure 1 displays an example with $n = 7$ and $h = 2$. Clearly, the end point of P is $(n, n - 2h)$. We call a lattice path which starts in $(0, 0)$ and never goes below the x -axis a *ballot path*. (This terminology is motivated by its relation to the (two-candidate) *ballot problem*, see e.g. [37, Ch. 1, Sec. 1]. An alternative term for ballot path which is often used is “Dyck path”, see e.g. [57, p. I-12].) We will use the abbreviation “b.p.” for “ballot path” in displayed formulas.

Ballot paths

Figure 1

Given such a lattice path P , label the steps from 1 to n , as is indicated in Figure 1. Then define A_P to be set of all labels corresponding to the first h up-steps of P and B_P to be set of all labels corresponding to the h down-steps of P . In the example of Figure 1 we have for the choice $h = 2$ that $A_P = \{1, 3\}$ and $B_P = \{2, 5\}$. Thus, to each h and s , $0 \leq h \leq s \leq n - h$, and P as above we can associate the vector $v_{h,s}(A_P, B_P)$. In our running example of Figure 1 the vector $v_{2,3}(P)$ would hence be $v_{2,3}(\{1, 3\}, \{2, 5\})$,

the vector in (2.15). To have a more concise form of notation, we will write $v_{h,s}(P)$ for $v_{h,s}(A_P, B_P)$ from now on.

Lemma 4. *The set of vectors*

$$\{v_{h,s}(P) : 0 \leq h \leq s \leq n - h, P \text{ a ballot path from } (0,0) \text{ to } (n, n - 2h)\} \quad (2.16)$$

is linearly independent.

The final Lemma tells us how many such vectors $v_{h,s}(P)$ there are.

Lemma 5. *The number of ballot paths from $(0,0)$ to $(n, n - 2h)$ is $\frac{n-2h+1}{n+1} \binom{n+1}{h}$. The total number of all vectors in the set (2.16) is 2^n .*

Now, let us for a moment assume that Lemmas 3–5 are already proved. Then, Theorem 2 follows immediately, as it turns out.

PROOF OF THEOREM 2. Consider the set of vectors in (2.16). By Lemma 3 we know that it consists of eigenvectors for the matrix $\zeta_n(u)$. In addition, Lemma 4 tells us that this set of vectors is linearly independent. Furthermore, by Lemma 5 the number of vectors in this set is exactly 2^n , which is the dimension of the space where all these vectors are contained. Therefore, they must form a basis of the space.

Lemma 3 says more precisely that $v_{h,s}(P)$ is an eigenvector for the eigenvalue λ_h . From what we already know, this implies that for fixed h the set

$$\{v_{h,s}(P) : h \leq s \leq n - h, P \text{ a ballot path from } (0,0) \text{ to } (n, n - 2h)\}$$

forms a basis for the eigenspace corresponding to λ_h . Therefore, the dimension of the eigenspace corresponding to λ_h equals the number of possible numbers s times the number of possible lattice paths P . This is exactly

$$(n - 2h + 1) \frac{(n - 2h + 1)}{(n + 1)} \binom{n + 1}{h},$$

the number of possible lattice paths P being given by the first statement of Lemma 5. This expression equals exactly the expression (2.13). Thus, Theorem 2 is proved. \square

Now we turn to the proofs of the Lemmas.

PROOF OF LEMMA 3. Let h, s and A, B be fixed, satisfying the restrictions in the statement of the Lemma. We have to show that

$$\zeta_n(u) \cdot v_{h,s}(A, B) = \lambda_h v_{h,s}(A, B).$$

Restricting our attention to the I -th component, we see from the definition (2.14) of $v_{h,s}(A, B)$ that we need to establish

$$\sum_{\substack{X \subseteq A \\ Y \subseteq [n] \setminus (A \cup B), |Y| = s - h}} Z_{I, X \cup X' \cup Y} (-1)^{|X|} = \begin{cases} \lambda_h (-1)^{|U|} & \text{if } I \text{ is of the form } U \cup U' \cup V \\ & \text{for some } U \text{ and } V, U \subseteq A, \\ & V \subseteq [n] \setminus (A \cup B), |V| = s - h \\ 0 & \text{otherwise.} \end{cases} \quad (2.17)$$

We prove (2.17) by a case by case analysis. The first two cases cover the case “otherwise” in (2.17), the third case treats the first alternative in (2.17).

Case 1. *The cardinality of I is different from s .* As we observed earlier, the cardinality of any set $X \cup X' \cup Y$ which occurs as index at the left-hand side of (2.17) equals s .

The cardinality of I however is different from s . As we observed in the Remark after Theorem 1, this implies that any coefficient $Z_{I, X \cup X' \cup Y}$ on the left-hand side vanishes. Thus, (2.17) is proved in this case.

Case 2. The cardinality of I equals s , but I does not have the form $U \cup U' \cup V$ for any U and V , $U \subseteq A$, $V \subseteq [n] \setminus (A \cup B)$, $|V| = s - h$. Now the sum on the left-hand side of (2.17) contains nonzero contributions. We have to show that they cancel each other. We do this by grouping summands in pairs, the sum of each pair being 0.

Consider a set $X \cup X' \cup Y$ which occurs as index at the left-hand side of (2.17). Let e be minimal such that

- either: the e -th largest element of A and the e -th largest element of B are both in I ,
- or: the e -th largest element of A and the e -th largest element of B are both not in I .

That such an e must exist is guaranteed by our assumptions about I . Now consider X and X' . If the e -th largest element of A is contained in X then the e -th largest element of B is not contained in X' , and vice versa. Define a new set \bar{X} by adding to X the e -th largest element of A if it is not already contained in X , respectively by removing it from X if it is contained in X . Then, it is easily checked that

$$Z_{I, X \cup X' \cup Y} = Z_{I, \bar{X} \cup \bar{X}' \cup Y}.$$

On the other hand, we have $(-1)^{|X|} = -(-1)^{|\bar{X}|}$ since the cardinalities of X and \bar{X} differ by ± 1 . Both facts combined give

$$Z_{I, X \cup X' \cup Y} (-1)^{|X|} + Z_{I, \bar{X} \cup \bar{X}' \cup Y} (-1)^{|\bar{X}|} = 0.$$

Hence, we have found two summands on the left-hand side of (2.17) which cancel each other.

Summarizing, this construction finds for any X, Y sets \bar{X}, Y such that the corresponding summands on the left-hand side of (2.17) cancel each other. Moreover, this construction applied to \bar{X}, Y gives back X, Y . Hence, what the construction does is exactly what we claimed, namely it groups the summands into pairs which contribute 0 to the whole sum. Therefore the sum is 0, which establishes (2.17) in this case also.

Case 3. I has the form $U \cup U' \cup V$ for some U and V , $U \subseteq A$, $V \subseteq [n] \setminus (A \cup B)$, $|V| = s - h$. This assumption implies in particular that the cardinality of I is s . From the Remark after the statement of Theorem 1 we know that in our situation $Z_{I, X \cup X' \cup Y}$ depends only on the number of common elements in I and $X \cup X' \cup Y$. Thus, the left-hand side in (2.17) reduces to

$$\sum_{j, k \geq 0} N(j, k) (-1)^{|U|+j} k! \frac{1}{2^n} \frac{\Gamma\left(\frac{5}{2} - u\right) \Gamma(2 + n - s - u) \Gamma(2 + s - u)}{\Gamma\left(\frac{5}{2} + \frac{n}{2} - u\right) \Gamma\left(2 + \frac{n}{2} - u\right) \Gamma(2 + k - u)}, \quad (2.18)$$

where $N(j, k)$ is the number of sets $X \cup X' \cup Y$, for some X and Y , $X \subseteq A$, $Y \subseteq [n] \setminus (A \cup B)$, $|Y| = s - h$, which have $s - k$ elements in common with I , and which have $h - j$ elements in common with $I \cap (A \cup B) = U \cup U'$. Clearly, we used expression (2.2) with $n_{\in \in} = s - k$ and $n_{\notin \in} = n - s - k$.

To determine $N(j, k)$, note first that there are $\binom{h}{j}$ possible sets $X \cup X'$ which intersect $U \cup U'$ in exactly $h - j$ elements. Next, let us assume that we already made a choice for $X \cup X'$. In order to determine the number of possible sets Y such that $X \cup X' \cup Y$ has

$s - k$ elements in common with I , we have to choose $(s - k) - (h - j) = s - h + j - k$ elements from V , for which we have $\binom{s-h}{s-h+j-k}$ possibilities, and we have to choose $s - h - (s - h + j - k) = k - j$ elements from $[n] \setminus (I \cup A \cup B)$ to obtain a total number of s elements, for which we have $\binom{n-s-h}{k-j}$ possibilities. Hence,

$$N(j, k) = \binom{h}{j} \binom{s-h}{k-j} \binom{n-s-h}{k-j}. \quad (2.19)$$

So it remains to evaluate the double sum (2.18), using the expression (2.19) for $N(j, k)$.

We start by writing the sum over j in (2.18) in hypergeometric notation,

$$\begin{aligned} & (-1)^{|U|} \frac{1}{2^n} \frac{\Gamma(\frac{5}{2} - u) \Gamma(2 + n - s - u) \Gamma(2 + s - u)}{\Gamma(2 - u) \Gamma(2 + \frac{n}{2} - u) \Gamma(\frac{5}{2} + \frac{n}{2} - u)} \\ & \times \sum_{k=0}^{\infty} \frac{(h-s)_k (h-n+s)_k}{(1)_k (2-u)_k} {}_3F_2 \left[\begin{matrix} -k, -k, -h \\ 1-h-k+s, 1-h-k+n-s \end{matrix}; 1 \right]. \end{aligned}$$

To the ${}_3F_2$ series we apply a transformation formula of Thomae (see e.g. [24, (3.1.1)]),

$${}_3F_2 \left[\begin{matrix} a, b, -m \\ d, e \end{matrix}; 1 \right] = \frac{(-b+e)_m}{(e)_m} {}_3F_2 \left[\begin{matrix} -m, b, -a+d \\ d, 1+b-e-m \end{matrix}; 1 \right] \quad (2.20)$$

where m is a nonnegative integer. We write the resulting ${}_3F_2$ again as a sum over j , then interchange sums over k and j , and write the (now) inner sum over k in hypergeometric notation. Thus we obtain

$$\begin{aligned} & (-1)^{|U|} \frac{1}{2^n} \frac{\Gamma(\frac{5}{2} - u) \Gamma(2 + n - s - u) \Gamma(2 + s - u)}{\Gamma(\frac{5}{2} + \frac{n}{2} - u) \Gamma(2 + \frac{n}{2} - u) \Gamma(2 - u)} \\ & \times \sum_{j=0}^{\infty} \frac{(-h)_j (1-h+s)_j}{(1)_j (2-u)_j} {}_2F_1 \left[\begin{matrix} j-n+s, h-s \\ 2+j-u \end{matrix}; 1 \right]. \end{aligned}$$

The ${}_2F_1$ series in this expression is terminating because $h - s$ is a nonpositive integer. Hence, it can be summed by means of Gauß' sum (2.10). Writing the remaining sum over j in hypergeometric notation, the above expression becomes

$$(-1)^{|U|} \frac{1}{2^n} \frac{\Gamma(\frac{5}{2} - u) \Gamma(2 + n - h - u) \Gamma(2 + s - u)}{\Gamma(\frac{5}{2} + \frac{n}{2} - u) \Gamma(2 + \frac{n}{2} - u) \Gamma(2 + s - h - u)} {}_2F_1 \left[\begin{matrix} -h, 1-h+s \\ 2-h+s-u \end{matrix}; 1 \right].$$

Again, the ${}_2F_1$ series is terminating and so is summable by means of (2.10). Thus, we get

$$(-1)^{|U|} \frac{1}{2^n} \frac{\Gamma(\frac{5}{2} - u) \Gamma(2 + n - h - u) \Gamma(1 + h - u)}{\Gamma(\frac{5}{2} + \frac{n}{2} - u) \Gamma(2 + \frac{n}{2} - u) \Gamma(1 - u)},$$

which is exactly the expression (2.12) for λ_h times $(-1)^{|U|}$. This proves (2.17) in this case.

The proof of Lemma 3 is now complete. \square

PROOF OF LEMMA 4. We know from Lemma 3 that $v_{h,s}(P)$ lies in the eigenspace for the eigenvalue λ_h , with λ_h being given in (2.12). The λ_h 's, $h = 0, 1, \dots, \lfloor n/2 \rfloor$,

are all distinct, so the corresponding eigenspaces are linearly independent. Therefore it suffices to show that for any *fixed* h the set of vectors

$$\{v_{h,s}(P) : h \leq s \leq n - h, P \text{ a ballot path from } (0,0) \text{ to } (n, n - 2h)\}$$

is linearly independent.

On the other hand, a vector $v_{h,s}(A, B)$ lies in the space spanned by the standard unit vectors e_T with $|T| = s$. Clearly, as s varies, these spaces are linearly independent. Therefore, it suffices to show that for any *fixed* h and s the set of vectors

$$\{v_{h,s}(P) : P \text{ a ballot path from } (0,0) \text{ to } (n, n - 2h)\}$$

is linearly independent.

So, let us fix integers h and s with $0 \leq h \leq s \leq n - h$, and let us suppose that there is some vanishing linear combination

$$\sum_{P \text{ b.p. from } (0,0) \text{ to } (n, n-2h)} c_P v_{h,s}(P) = 0. \quad (2.21)$$

We have to establish that $c_P = 0$ for all ballot paths P from $(0,0)$ to $(n, n - 2h)$.

We prove this fact by induction on the set of ballot paths from $(0,0)$ to $(n, n - 2h)$. In order to make this more precise, we need to impose a certain order on the ballot paths. Given a ballot path P from $(0,0)$ to $(n, n - 2h)$, we define its *front portion* F_P to be the portion of P from the beginning up to and including P 's h -th up-step. For example, choosing $h = 2$, the front portion of the ballot path in Figure 1 is the subpath from $(0,0)$ to $(3,1)$. Note that F_P can be any ballot path starting in $(0,0)$ with h up-steps and less than h down-steps. We order such front portions lexicographically, in the sense that F_1 is before F_2 if and only if F_1 and F_2 agree up to some point and then F_1 continues with an up-step while F_2 continues with a down-step.

Now, here is what we are going to prove: Fix any possible front portion F . We shall show that $c_P = 0$ for all P with front portion F_P equal to F , *given that it is already known that $c_{P'} = 0$ for all P' with a front portion $F_{P'}$ that is before F* . Clearly, by induction, this would prove $c_P = 0$ for *all* ballot paths P from $(0,0)$ to $(n, n - 2h)$.

Let F be a possible front portion, i.e., a ballot path starting in $(0,0)$ with exactly h up-steps and less than h down-steps. As we did earlier, label the steps of F by $1, 2, \dots$, and denote the set of labels corresponding to the down-steps of F by B_F . We write b for $|B_F|$, the number of all down-steps of F . Observe that then the total number of steps of F is $h + b$.

Now, let T be a fixed $(h-b)$ -element subset of $\{h+b+1, h+b+2, \dots, n\}$. Furthermore, let S be a set of the form $S = B_F \cup S_1 \cup S_2$, where $S_1 \subseteq T$ and $S_2 \subseteq \{h+b+1, h+b+2, \dots, n\} \setminus T$, and such that $|S| = s$.

We consider the coefficient of e_S in the left-hand side of (2.21). To determine this coefficient, we have to determine the coefficient of e_S in $v_{h,s}(P)$, for all P . We may concentrate on those P whose front portion F_P is equal to or later than F , since our induction hypothesis says that $c_P = 0$ for all P with F_P before F . So, let P be a ballot path from $(0,0)$ to $(n, n - 2h)$ with front portion equal to or later than F . We claim that the coefficient of e_S in $v_{h,s}(P)$ is zero unless the set B_P of down-steps of P is contained in S .

Let the coefficient of e_S in $v_{h,s}(P)$ be nonzero. To establish the claim, we first prove that the front portion F_P of P has to equal F . Suppose that this is not the case. Then

the front portion of P runs in parallel with F for some time, say for the first $(m-1)$ steps, with some $m \leq h+b$, and then F continues with an up-step and F_P continues with a down-step (recall that F_P is equal to or later than F). By (2.14) we have

$$v_{h,s}(P) := \sum_{\substack{X \subseteq A_P \\ Y \subseteq [n] \setminus (A_P \cup B_P), |Y|=s-h}} (-1)^{|X|} e_{X \cup X' \cup Y}. \quad (2.22)$$

We are assuming that the coefficient of e_S in $v_{h,s}(P)$ is nonzero, therefore S must be of the form $S = X \cup X' \cup Y$, with X, Y as described in (2.22). We are considering the case that the m -th step of F_P is a down-step, whence $m \in B_P$, while the m -th step of F is an up-step, whence $m \notin B_F$. By definition of S , we have $S \cap \{1, 2, \dots, h+b\} = B_F$, whence $m \notin S$.

Summarizing so far, we have $m \in B_P$, $m \notin S$, for some $m \leq h+b$, and $S = X \cup X' \cup Y$, for some X, Y as described in (2.22). In particular we have $m \notin X'$. Now recall that X' is the “complement of X in B_P ”. This says in particular that, if m is the i -th largest element in B_P , then the i -th largest element of A_P , a say, is an element of X , and so of S . By construction of A_P and B_P , a is smaller than m , so in particular $a < h+b$. As we already observed, there holds $S \cap \{1, 2, \dots, h+b\} = B_F$, so we have $a \in B_F$, i.e., the a -th step of F is a down-step. On the other hand, we assumed that P and F run in parallel for the first $(m-1)$ steps. Since $a \in A_P$, the set of up-steps of P , the a -th step of P is an up-step. We have $a \leq m-1$, therefore the a -th step of F must be an up-step also. This is absurd. Therefore, given that the coefficient of e_S in $v_{h,s}(P)$ is nonzero, the front portion F_P of P has to equal F .

Now, let P be a ballot path from $(0,0)$ to $(n, n-2h)$ with front portion equal to F , and suppose that S has the form $S = X \cup X' \cup Y$, for some X, Y as described in (2.22). By definition of the front portion, the set A_P of up-steps of P has the property $A_P \cap \{1, 2, \dots, h+b\} = \{1, 2, \dots, h+b\} \setminus B_F$. Since $|B_F| = b$, these are the labels of exactly h up-steps. Since the cardinality of A_P is exactly h by definition, we must have $A_P = \{1, 2, \dots, h+b\} \setminus B_F$. Because of $S \cap \{1, 2, \dots, h+b\} = B_F$, which we already used a number of times, A_P and S are disjoint, which in particular implies that A_P and X are disjoint. However, X is a subset of A_P by definition, so X must be empty. This in turn implies that $X' = B_P$. This says nothing else but that the set B_P of down-steps of P equals X' and so is contained in S . This establishes our claim.

In fact, we proved more. We saw that S has the form $S = X \cup X' \cup Y$, with $X = \emptyset$. This implies that the coefficient of e_S in $v_{h,s}(P)$, as given by (2.22), is actually $+1$. Comparison of coefficients of e_S in (2.21) then gives

$$\sum_{\substack{P \text{ b.p. from } (0,0) \text{ to } (n, n-2h) \\ F_P = F, B_P \subseteq S}} c_P = 0, \quad (2.23)$$

for any $S = B_F \cup S_1 \cup S_2$, where $S_1 \subseteq T$ and $S_2 \subseteq \{h+b+1, h+b+2, \dots, n\} \setminus T$, and such that $|S| = s$.

Now, we sum both sides of (2.23) over all such sets S , keeping the cardinality of S_1 and S_2 fixed, say $|S_1| = h-b-j$, enforcing $|S_2| = s-h+j$, for a fixed j , $0 \leq j \leq h-b$. For a fixed ballot path P from $(0,0)$ to $(n, n-2h)$, with front portion F , with $h-b-k$ down-steps in T , and hence with k down-steps in $\{h+b+1, h+b+2, \dots, n\} \setminus T$, there are $\binom{k}{h-b-j}$ such sets $S_1 \subseteq T$ containing all the $h-b-k$ down-steps of P in T , and there

are $\binom{n-(h+b)-(h-b)-k}{s-h+j-k}$ such sets $S_2 \subseteq \{h+b+1, h+b+2, \dots, n\} \setminus T$ containing all the down-steps of P in $\{h+b+1, h+b+2, \dots, n\} \setminus T$. Therefore, summing up (2.23) gives

$$\sum_{k \geq 0} \binom{k}{j} \binom{n-2h-k}{n-h-s-j} \left(\sum_{\substack{P \text{ b.p. from } (0,0) \text{ to } (n, n-2h) \\ F_P=F, |B_P \cap T|=h-b-k \\ |B_P \cap (\{h+b+1, h+b+2, \dots, n\} \setminus T)|=k}} c_P \right) = 0, \quad j = 0, 1, \dots, h-b. \quad (2.24)$$

Denoting the inner sum in (2.24) by $C(k)$, we see that (2.24) represents a non-degenerate triangular system of linear equations for $C(0), C(1), \dots, C(h-b)$. Therefore, all the quantities $C(0), C(1), \dots, C(h-b)$ have to equal 0. In particular, we have $C(0) = 0$. Now, $C(0)$ consists of just a single term c_P , with P being the ballot path from $(0,0)$ to $(n, n-2h)$, with front portion F , and the labels of the $h-b$ down-steps besides those of F being exactly the elements of T . Therefore, we have $c_P = 0$ for this ballot path. The set T was an arbitrary $(h-b)$ -subset of $\{h+b+1, h+b+2, \dots, n\}$. Thus, we have proved $c_P = 0$ for any ballot path P from $(0,0)$ to $(n, n-2h)$ with front portion F . This completes our induction proof. \square

PROOF OF LEMMA 5. That the number of ballot paths from $(0,0)$ to $(n, n-2h)$ equals $\frac{n-2h+1}{n+1} \binom{n+1}{h}$ is a classical combinatorial result (see e.g. [37, Theorem 1 with $t = 1$]). From this it follows that the total number of vectors in the set (2.16) is

$$\sum_{h=0}^{\lfloor n/2 \rfloor} (n-2h+1) \frac{(n-2h+1)}{(n+1)} \binom{n+1}{h}. \quad (2.25)$$

To evaluate this sum, note that the summand is invariant under the substitution $h \rightarrow n-2h+1$. Therefore, extending the range of summation in (2.25) to $h = 0, 1, \dots, n+1$ and dividing the result by 2 gives the same value. So, the cardinality of the set (2.16) is also given by

$$\frac{1}{2} \sum_{h=0}^{n+1} \frac{(n-2h+1)^2}{(n+1)} \binom{n+1}{h}.$$

The reader will not have any difficulty in splitting this sum into three parts so that each part can be summed by means of the binomial theorem. (Computer algebra systems like *Maple* or *Mathematica* do this automatically.) The result is exactly 2^n , as was claimed. \square

In fact, Theorem 2 can be generalized to a wider class of matrices.

Theorem 6. Let $\tilde{\zeta}_n(u) = (\tilde{Z}_{IJ})_{I,J \in [n]}$ be the $2^n \times 2^n$ matrix defined by

$$\tilde{Z}_{IJ} := \delta_{n_{\notin \in}, n_{\notin \notin}} \frac{\left(\frac{n - n_{\in \in} - n_{\notin \notin}}{2} \right)!}{\Gamma \left(2 + \frac{n - n_{\in \in} - n_{\notin \notin}}{2} - u \right)} \cdot f(n_{\in \in} - n_{\notin \notin}),$$

where $n_{\in \in}$, etc., have the same meaning as earlier, and where $f(x)$ is a function of x which is symmetric, i.e., $f(x) = f(-x)$. Then, the eigenvalues of $\tilde{\zeta}_n(u)$ are

$$\lambda_{h,s} = f(n-2s) \frac{\Gamma(2+n-h-u) \Gamma(1+h-u)}{\Gamma(2+n-s-u) \Gamma(2+s-u) \Gamma(1-u)}, \quad 0 \leq h \leq s \leq n-h, \quad (2.26)$$

with respective multiplicities

$$\frac{n-2h+1}{n+1} \binom{n+1}{h}, \quad (2.27)$$

independent of s .

PROOF. The above proof of Theorem 2 has to be adjusted only insignificantly to yield a proof of Theorem 6. In particular, the vector $v_{h,s}(A, B)$ as defined in (2.14) is an eigenvector for $\lambda_{h,s}$, for any two disjoint h -element subsets A and B of $[n]$, and the set (2.16) is a basis of eigenvectors for $\tilde{\zeta}_n(u)$. \square

2.3. The relative entropies of $\otimes^n \rho$ with respect to the Bayesian density matrices $\zeta_n(u)$. We now apply the preceding results to compute the relative entropy $S(\otimes^n \rho, \zeta_n(u))$ of $\otimes^n \rho$ with respect to $\zeta_n(u)$. Utilizing the definition (1.3) of relative entropy and employing the property [38, 59] that $S(\otimes^n \rho) = nS(\rho)$, it is given by

$$-nS(\rho) - \text{Tr} \left(\otimes^n \rho \cdot \log \zeta_n(u) \right). \quad (2.28)$$

For the first term, for the entropy $S(\rho)$ of ρ , ρ being given by (1.4), we have, using spherical coordinates (r, ϑ, ϕ) , so that $r = (x^2 + y^2 + z^2)^{1/2}$,

$$S(\rho) = -\frac{(1-r)}{2} \log \frac{(1-r)}{2} - \frac{(1+r)}{2} \log \frac{(1+r)}{2}. \quad (2.29)$$

Concerning the second term in (2.28), we have the following theorem.

Theorem 7. *Let $\zeta_n(u) = (Z_{IJ})_{I,J \in [n]}$ be the matrix with entries Z_{IJ} given in (2.2). Then, we have*

$$\begin{aligned} & \text{Tr} \left(\otimes^n \rho \cdot \log \zeta_n(u) \right) \\ &= \sum_{h=0}^{\lfloor n/2 \rfloor} \frac{n-2h+1}{n+1} \binom{n+1}{h} \frac{1}{2^{n+1}r} \left((1+r)^{n+1-h}(1-r)^h - (1+r)^h(1-r)^{n+1-h} \right) \log \lambda_h, \end{aligned} \quad (2.30)$$

with λ_h as given in (2.12), and with $r = \sqrt{x^2 + y^2 + z^2}$.

Before we move on to the proof, we note that Theorem 7 gives us the following expression for the relative entropy of $\otimes^n \rho$ with respect to $\zeta_n(u)$

Corollary 8. *The relative entropy $S(\otimes^n \rho, \zeta_n(u))$ of $\otimes^n \rho$ with respect to $\zeta_n(u)$ equals*

$$\begin{aligned} & \frac{n}{2}(1-r) \log((1-r)/2) + \frac{n}{2}(1+r) \log((1+r)/2) \\ & - \sum_{h=0}^{\lfloor n/2 \rfloor} \frac{(n-2h+1)}{(n+1)} \binom{n+1}{h} \\ & \quad \cdot \frac{1}{2^{n+1}r} \left((1+r)^{n-h+1}(1-r)^h - (1+r)^h(1-r)^{n-h+1} \right) \log \lambda_h, \end{aligned} \quad (2.31)$$

with λ_h as given in (2.12), and with $r = \sqrt{x^2 + y^2 + z^2}$.

PROOF OF THEOREM 7. One way of determining the trace of a linear operator L is to choose a basis of the vector space, $\{v_I : I \in [n]\}$ say, write the action of L on the basis elements in the form

$$Lv_I = c_I v_I + \text{linear combination of } v_J\text{'s, } J \neq I,$$

and then form the sum $\sum_I c_I$ of the “diagonal” coefficients, which gives exactly the trace of L .

Clearly, we choose as a basis our set (2.16) of eigenvectors for $\zeta_n(u)$. To determine the action of $\otimes \rho \cdot \log \zeta_n(u)$ we need only to find the action of $\otimes \rho$ on the vectors in the set (2.16). We claim that this action can be described as

$$\begin{aligned} & \left(\otimes \rho \right) \cdot v_{h,s}(P) \\ &= \frac{1}{2^n} \left(\sum_{k \geq j \geq 0} (-1)^j \binom{h}{j} \binom{s-h}{k-j} \binom{n-s-h}{k-j} (1+z)^{s-k} (x^2+y^2)^k (1-z)^{n-s-k} \right) \\ & \quad \cdot v_{h,s}(P) + \text{linear combination of eigenvectors} \\ & \quad v_{h',s'}(P') \text{ with } s' \neq s, \end{aligned} \quad (2.32)$$

for any basis vector $v_{h,s}(P)$ in (2.16).

To see this, consider the I -th component of $\left(\otimes \rho \right) \cdot v_{h,s}(P)$, i.e., the coefficient of e_I in $\left(\otimes \rho \right) \cdot v_{h,s}(P)$, $I \in [n]$. By the definition (2.14) of $v_{h,s}(P)$ it equals

$$\sum_{\substack{X \subseteq A_P \\ Y \subseteq [n] \setminus (A_P \cup B_P), |Y|=s-h}} R_{I, X \cup X' \cup Y} (-1)^{|X|}, \quad (2.33)$$

where R_{IJ} denotes the (I, J) -entry of $\otimes \rho$. (Recall that R_{IJ} is given explicitly in (2.1).) Now, it should be observed that we did a similar calculation already, namely in the proof of Lemma 3. In fact, the expression (2.33) is almost identical with the left-hand side of (2.17). The essential difference is that Z_{IJ} is replaced by R_{IJ} for all J (the nonessential difference is that A, B are replaced by A_P, B_P , respectively). Therefore, we can partially rely upon what was done in the proof of Lemma 3.

We distinguish between the same cases as in the proof of Lemma 3.

Case 1. The cardinality of I is different from s . We do not have to worry about this case, since e_I then lies in the span of vectors $v_{h',s'}(P')$ with $s' \neq s$, which is taken care of in (2.32).

Case 2. The cardinality of I equals s , but I does not have the form $U \cup U' \cup V$ for any U and V , $U \subseteq A_P$, $V \subseteq [n] \setminus (A_P \cup B_P)$, $|V| = s - h$. Essentially the same arguments as those in Case 2 in the proof of Lemma 3 show that the term (2.33) vanishes for this choice of I . Of course, one has to use the explicit expression (2.1) for R_{IJ} .

Case 3. I has the form $U \cup U' \cup V$ for some U and V , $U \subseteq A_P$, $V \subseteq [n] \setminus (A_P \cup B_P)$, $|V| = s - h$. In Case 3 in the proof of Lemma 3 we observed that there are $N(j, k)$ sets $X \cup X' \cup Y$, for some X and Y , $X \subseteq A_P$, $Y \subseteq [n] \setminus (A_P \cup B_P)$, $|Y| = s - h$, which have $s - k$ elements in common with I , and which have $h - j$ elements in common with $I \cap (A_P \cup B_P) = U \cup U'$, where $N(j, k)$ is given by (2.19). Then, using the explicit

expression (2.1) for R_{IJ} , it is straightforward to see that the expression (2.33) equals

$$\frac{1}{2^n} \sum_{k \geq j \geq 0} (-1)^{|U|+j} \binom{h}{j} \binom{s-h}{k-j} \binom{n-s-h}{k-j} (1+z)^{s-k} (x^2+y^2)^k (1-z)^{n-s-k}$$

in this case. This establishes (2.32).

Now we are in the position to write down an expression for the trace of $\otimes^n \rho \cdot \log \zeta_n(u)$. By Theorem 2 and by (2.32) we have

$$\begin{aligned} & \left(\otimes^n \rho \cdot \log \zeta_n(u) \right) \cdot v_{h,s}(P) \\ &= \frac{1}{2^n} \left(\sum_{k \geq j \geq 0} (-1)^j \binom{h}{j} \binom{s-h}{k-j} \binom{n-s-h}{k-j} (1+z)^{s-k} (x^2+y^2)^k (1-z)^{n-s-k} \right) \\ & \quad \cdot \log \lambda_h \cdot v_{h,s}(P) + \text{linear combination of eigenvectors} \\ & \quad v_{h',s'}(P') \text{ with } s' \neq s. \end{aligned} \quad (2.34)$$

From what was said at the beginning of this proof, in order to obtain the trace of $\otimes^n \rho \cdot \log \zeta_n(u)$, we have to form the sum of all the “diagonal” coefficients in (2.34). Using the first statement of Lemma 5 and replacing $x^2 + y^2$ by $r^2 - z^2$, we see that it is

$$\begin{aligned} & \sum_{h=0}^{\lfloor n/2 \rfloor} \log \lambda_h \frac{(n-2h+1)}{(n+1)} \binom{n+1}{h} \frac{1}{2^n} \sum_{s=h}^{n-h} \sum_{k \geq j \geq 0} (-1)^j \binom{h}{j} \binom{s-h}{k-j} \binom{n-s-h}{k-j} \\ & \quad \cdot (1+z)^{s-k} (r^2 - z^2)^k (1-z)^{n-s-k}. \end{aligned} \quad (2.35)$$

In order to see that this expression equals (2.30), we have to prove

$$\begin{aligned} & \sum_{s=h}^{n-h} \sum_{j=0}^h \sum_{k=j}^s (-1)^j \binom{h}{j} \binom{s-h}{k-j} \binom{n-s-h}{k-j} (1+z)^{s-k} (r^2 - z^2)^k (1-z)^{n-s-k} \\ &= \frac{1}{2r} ((1+r)^{n+1-h} (1-r)^h - (1+r)^h (1-r)^{n+1-h}). \end{aligned} \quad (2.36)$$

We start with the left-hand side of (2.36) and write the inner sum in hypergeometric notation, thus obtaining

$$\sum_{s=h}^{n-h} \sum_{j=0}^h (1-z)^{n-s-j} (1+z)^{s-j} (r^2 - z^2)^j \frac{(-h)_j}{(1)_j} {}_2F_1 \left[\begin{matrix} h-n+s, h-s \\ 1 \end{matrix}; \frac{r^2 - z^2}{1-z^2} \right].$$

To the ${}_2F_1$ series we apply the transformation formula ([49, (1.8.10), terminating form])

$${}_2F_1 \left[\begin{matrix} a, -m \\ c \end{matrix}; z \right] = \frac{(c-a)_m}{(c)_m} {}_2F_1 \left[\begin{matrix} -m, a \\ 1+a-c-m \end{matrix}; 1-z \right],$$

where m is a nonnegative integer. We write the resulting ${}_2F_1$ series again as a sum over k . In the resulting expression we exchange sums so that the sum over j becomes the innermost sum. Thus, we obtain

$$\begin{aligned} & \sum_{s=h}^{n-h} \sum_{k=0}^{s-h} (1-r^2)^k (1-z)^{n-s-k} (1+z)^{s-k} \\ & \quad \cdot \frac{(h-s)_k (n-h-s+1)_{s-h} (h-n+s)_k}{(1)_k (1)_{s-h} (2h-n)_k} \sum_{j=0}^h \binom{h}{j} \left(\frac{z^2 - r^2}{1-z^2} \right)^j. \end{aligned}$$

Clearly, the innermost sum can be evaluated by the binomial theorem. Then, we interchange sums over s and k . The expression that results is

$$\sum_{k=0}^{\lfloor n/2 \rfloor - h} (1-r^2)^{h+k} (1-z)^{n-2h-2k} \frac{(2h+k-n)_k}{(1)_k} \cdot \sum_{s=0}^{n-2h-2k} \binom{n-2h-2k}{s} \left(\frac{1+z}{1-z} \right)^s.$$

Again, we can apply the binomial theorem. Thus, we reduce our expression on the left-hand side of (2.36) to

$$2^{n-2h} (1-r^2)^h \sum_{k=0}^{\lfloor n/2 \rfloor - h} \frac{(h - \frac{n}{2})_k (h - \frac{n}{2} + \frac{1}{2})_k}{(2h-n)_k k!} (1-r^2)^k.$$

Now, we replace $(1-r^2)^k$ by its binomial expansion $\sum_{l=0}^k (-1)^l \binom{k}{l} r^{2l}$, interchange sums over k and l , and write the (now) inner sum over k in hypergeometric notation. This gives

$$2^{n-2h} (1-r^2)^h \left(\sum_{l=0}^{\lfloor n/2 \rfloor - h} (-1)^l r^{2l} \frac{(h - \frac{n}{2})_l (\frac{1}{2} + h - \frac{n}{2})_l}{(1)_l (2h-n)_l} \cdot {}_2F_1 \left[\begin{matrix} h+l - \frac{n}{2}, \frac{1}{2} + h + l - \frac{n}{2} \\ 2h+l-n \end{matrix}; 1 \right] \right).$$

Finally, this ${}_2F_1$ series can be summed by means of Gauß' summation (2.10). Simplifying, we have

$$(1-r^2)^h \sum_{l=0}^{\lfloor n/2 \rfloor - h} \binom{n-2h+1}{2l+1} r^{2l},$$

which is easily seen to equal the right-hand side in (2.36). This completes the proof of the Theorem. \square

2.4. Asymptotics of the relative entropy of $\otimes^n \rho$ with respect to $\zeta_n(u)$. In the preceding subsection, we obtained in Corollary 8 the general formula (2.31) for the relative entropy of $\otimes^n \rho$ with respect to the Bayesian density matrix $\zeta_n(u)$. We, now, proceed to find its asymptotics for $n \rightarrow \infty$. We prove the following theorem.

Theorem 9. *The asymptotics of the relative entropy $S(\otimes^n \rho, \zeta_n(u))$ of $\otimes^n \rho$ with respect to $\zeta_n(u)$ for a fixed $r = \sqrt{x^2 + y^2 + z^2}$ with $0 \leq r < 1$ is given by*

$$\begin{aligned} & \frac{3}{2} \log n - \frac{1}{2} - \frac{3}{2} \log 2 - (1-u) \log(1-r^2) + \frac{1}{2r} \log \left(\frac{1-r}{1+r} \right) \\ & + \log \Gamma(1-u) - \log \Gamma(5/2-u) + O\left(\frac{1}{n}\right). \end{aligned} \quad (2.37)$$

In the case $r = 0$, this means that the asymptotics is given by the expression (2.37) in the limit $r \downarrow 0$, i.e., by

$$\frac{3}{2} \log n - \frac{3}{2} - \frac{3}{2} \log 2 + \log \Gamma(1-u) - \log \Gamma(5/2-u) + O\left(\frac{1}{n}\right). \quad (2.38)$$

For any fixed $\varepsilon > 0$, the $O(\cdot)$ term in (2.37) is uniform in u and r as long as $0 \leq r \leq 1 - \varepsilon$.

For $r = 1$ the asymptotics is given by

$$(2 - u) \log n + (2u - 3) \log 2 + \frac{1}{2} \log \pi - \log \Gamma(5/2 - u) + O\left(\frac{1}{n}\right). \quad (2.39)$$

Also here, the $O(\cdot)$ term is uniform in u .

Remark. It is instructive to observe that, although a comparison of (2.37) and (2.39) seems to suggest that the asymptotics of the relative entropy of $\otimes^n \rho$ with respect to $\zeta_n(u)$ behaves completely differently for $0 \leq r < 1$ and $r = 1$, the two cases are really quite compatible. In fact, letting r tend to 1 in (2.37) shows that (ignoring the error term) the asymptotic expression approaches $+\infty$ for $u < 1/2$, $-\infty$ for $u > 1/2$, and it approaches $\frac{3}{2} \log n - \frac{1}{2} - \frac{5}{2} \log 2 + \frac{1}{2} \log \pi$ for $u = 1/2$. This indicates that, for $r = 1$, the order of magnitude of the relative entropy of $\otimes^n \rho$ with respect to $\zeta_n(u)$ should be larger than $\frac{3}{2} \log n$ if $u < 1/2$, smaller than $\frac{3}{2} \log n$ if $u > 1/2$, and exactly $\frac{3}{2} \log n$ if $u = 1/2$. How much larger or smaller is precisely what formula (2.39) tells us: the order of magnitude is $(2 - u) \log n$, and in the case $u = 1/2$ the asymptotics is, in fact, $\frac{3}{2} \log n - 2 \log 2 + \frac{1}{2} \log \pi$.

SKETCH OF PROOF OF THEOREM 9. We have to estimate the expression (2.31) for large n . Clearly, it suffices to concentrate on the sum in (2.31). Because of $\lambda_{n+1-h} = \lambda_h$, this sum can be also expressed as

$$\frac{1}{2^{n+1}r} \sum_{h=0}^{n+1} \frac{(n-2h+1)}{(n+1)} \binom{n+1}{h} (1+r)^{n-h+1} (1-r)^h \log \lambda_h. \quad (2.40)$$

For $r = 1$ this sum reduces to $\log \lambda_0$, λ_0 being given by (2.12). A straightforward application of Stirling's formula then leads to (2.39).

From now on let $0 \leq r < 1$. We recall that λ_h is given by (2.12). Consequently, we expand the logarithm in (2.40) according to the addition rule, and split the sum (2.40) into the corresponding parts. The individual parts can be summed by means of the binomial theorem, except for the parts which involve $\log \Gamma(1+h-u)$. (To be precise, they have to be split appropriately before the binomial theorem can be applied. Computer algebra systems like *Maple* or *Mathematica* do this automatically.)

In order to handle the terms which contain $\log \Gamma(1+h-u)$, we use Stirling's formula

$$\log \Gamma(z) = \left(z - \frac{1}{2}\right) \log(z) - z + \frac{1}{2} \log 2 + \frac{1}{2} \log \pi + O\left(\frac{1}{z}\right). \quad (2.41)$$

Again, after splitting, all the resulting sums can be evaluated by means of the binomial theorem, except for

$$\frac{1}{2^{n+1}r} \sum_{h=0}^{n+1} \frac{(n-2h+1)}{(n+1)} \binom{n+1}{h} (1+r)^{n+1-h} (1-r)^h (1/2 - u + h) \log(1+h-u). \quad (2.42)$$

The asymptotics of this sum can now easily (if though tediously) be determined by making use of a Taylor expansion of $\log(1+h-u)$ about $n(1-r)/2$ (i.e., at $1+h-u = n(1-r)/2$) with sufficiently many terms.

If everything is put together, the result is (2.37). \square

2.5. Asymptotics of the von Neumann entropies of the Bayesian density matrices $\zeta_n(u)$. The main result of this section describes the asymptotics of the von Neumann entropy (1.10) of $\zeta_n(u)$. In view of the explicit description of the eigenvalues of $\zeta_n(u)$ and their multiplicities in Theorem 2, this entropy equals

$$- \sum_{h=0}^{\lfloor n/2 \rfloor} \frac{(n-2h+1)^2}{(n+1)} \binom{n+1}{h} \lambda_h \log \lambda_h, \quad (2.43)$$

with λ_h being given by (2.12).

Theorem 10. *The asymptotics of the von Neumann entropy $S(\zeta_n(u))$ of $\zeta_n(u)$ is given by*

$$\begin{aligned} n \left(\frac{-7+5u}{2(2-u)(1-u)} + \psi(5-2u) - \psi(1-u) \right) + \frac{3}{2} \log n + \left(-\frac{7}{2} + 2u \right) \log 2 \\ - \frac{14-20u+7u^2}{2(2-u)(1-u)} + \log(\Gamma(1-u)) - \log(\Gamma(5/2-u)) \\ + (2-2u)(\psi(5-2u) - \psi(1-u)) + O\left(\frac{1}{n^{1-u}}\right), \end{aligned} \quad (2.44)$$

where $\psi(x)$ is the digamma function,

$$\psi(x) = \frac{\frac{d}{dx}\Gamma(x)}{\Gamma(x)}.$$

SKETCH OF PROOF. We have to estimate the expression (2.43) for large n . We proceed as in the proof of Theorem 9. First we use the property $\lambda_{n+1-h} = \lambda_h$ to rewrite the sum (2.43) as

$$- \frac{1}{2} \sum_{h=0}^{n+1} \frac{(n-2h+1)^2}{(n+1)} \binom{n+1}{h} \lambda_h \log \lambda_h. \quad (2.45)$$

Next, while recalling that λ_h is given by (2.12), we expand the logarithm in (2.45) according to the addition rule, and split the sum (2.45) into the corresponding parts. Here, the individual parts can be summed by means of Gauß' ${}_2F_1$ summation (2.10), except for the parts which involve $\log \Gamma(1+h-u)$. (Again, to be precise, they have to be split appropriately before the Gauß summation can be applied, which is done automatically by computer algebra systems like *Maple* or *Mathematica*.)

To handle the terms which contain $\log \Gamma(1+h-u)$, we invoke again Stirling's formula (2.41). After splitting, all the resulting sums can be evaluated by means of Gauß' ${}_2F_1$ summation (2.10), except for

$$\sum_{h=0}^{n+1} \frac{(n-2h+1)^2}{(n+1)} \binom{n+1}{h} \lambda_h (1/2 + h - u) \log(1+h-u). \quad (2.46)$$

Now, to get an asymptotic estimate for this sum, as n tends to infinity, is not as obvious as it was for (2.42). The essential “trick” needed was kindly indicated to us by Peter Grabner: an asymptotic estimate (in fact, an exact result) for (2.46) with $\log(1+h-u)$ replaced by $\psi(1+h-u)$ can be obtained without difficulty (but with some amount of

tedious calculation) by starting with the sum

$$\sum_{h=0}^{n+1} \frac{(n-2h+1)^2}{(n+1)} \binom{n+1}{h} \cdot \frac{1}{2^n} \frac{\Gamma(5/2-u) \Gamma(2+n-h-u) \Gamma(1+\alpha+h-u)}{\Gamma(5/2+n/2-u) \Gamma(2+n/2-u) \Gamma(1-u)} (h-u+1/2), \quad (2.47)$$

evaluating it by applying Gauß' ${}_2F_1$ summation (2.10), differentiating both sides of the resulting equation with respect to α , and by finally setting $\alpha = 0$. Finally one relates the result to (2.46) by using the asymptotic expansion $\psi(z) = \log(z) - \frac{1}{2z} + O\left(\frac{1}{z^2}\right)$.

If everything is put together, the right-hand side of (2.44) is obtained. \square

Figure 2

3. COMPARISON OF OUR ASYMPTOTIC REDUNDANCIES FOR THE ONE-PARAMETER FAMILY q_u WITH THOSE OF CLARKE AND BARRON

Let us, first, compare the formula (1.1) for the asymptotic redundancy of Clarke and Barron to that derived here (2.37) for the two-level quantum systems, in terms of the one-parameter family of probability densities q_u , $-\infty < u < 1$, given in (1.7). Since the unit ball or Bloch sphere of such systems is three-dimensional in nature, we are led to set the dimension d of the parameter space in (1.1) to 3. The quantum Fisher information matrix $I(\theta)$ for that case was taken to be (1.5), while the role of the probability function $w(\theta)$ is played by q_u . Under these substitutions, it was seen in the Introduction that formula (1.1) reduces to (1.8). Then, we see that for $0 \leq r < 1$, formulas (2.37) and (1.8) coincide except for the presence of the monotonically increasing (nonclassical/quantum) term

$$-\frac{1}{2} \log(1-r^2) + \frac{1}{2r} \log\left(\frac{1-r}{1+r}\right) = \frac{1}{2r} ((1-r)\log(1-r) - (1+r)\log(1+r))$$

(see Figure 2 for a plot of this term — $\log 2 \approx .693147$ “nats” of information equalling one “bit”) in (2.37). (This term would have to be replaced by -1 — that is, its limit for $r \rightarrow 0$ — to give (1.8).) In particular, the order of magnitude, $\frac{3}{2} \log n$, is precisely the same in both formulas. For the particular case $r = 0$, the asymptotic formula (2.37) (see (2.38)) precisely coincides with (1.8).

In the case $r = 1$, however, i.e., when we consider the boundary of the parameter space (represented by the unit sphere), the situation is slightly tricky. Due to the fact that the formula of Clarke and Barron holds only for interior points of the parameter space, we cannot expect that, in general, our formula will resemble that of Clarke and Barron. However, if the probability density, q_u , is concentrated on the boundary of the sphere, then we may disregard the interior of the sphere, and consider the boundary of the sphere as the *true* parameter space. This parameter space is *two-dimensional* and consists of interior points throughout. Indeed, the probability density q_u is concentrated on the boundary of the sphere if we choose $u = 1$ since, as we remarked in the Introduction, in the limit $u \rightarrow 1$, the distribution determined by q_u tends to the uniform distribution over the boundary of the sphere. Let us, again, (naively) attempt to apply Clarke and Barron’s formula (1.1) to that case. We parameterize the boundary of the sphere by polar coordinates (ϑ, ϕ) ,

$$\begin{aligned} x &= \sin \vartheta \cos \varphi \\ y &= \sin \vartheta \sin \varphi \\ z &= \cos \vartheta, \\ 0 &\leq \varphi \leq 2\pi, \quad 0 \leq \vartheta \leq \pi. \end{aligned}$$

The probability density induced by q_u in the limit $u \rightarrow 1$ then is $\sin \vartheta / 4\pi$, the density of the uniform distribution. Using [22, eq. (8)] (see footnote 2), the quantum (symmetric logarithmic derivative) Fisher information matrix turns out to be

$$\begin{pmatrix} 1 & 0 \\ 0 & \sin^2 \vartheta \end{pmatrix}, \quad (3.1)$$

its determinant equalling, therefore, $\sin^2 \vartheta$. So, setting $d = 2$ and substituting $\sin \vartheta / 4\pi$ for $w(\theta)$ and $\sin^2 \vartheta$ for $I(\theta)$ in (1.1) gives $\log n + \log 2 - 1$. On the other hand, our formula (2.39), for $u = 1$, gives $\log n$. So, again, the terms differ only by a constant. In particular, the order of magnitude is again the same.

Let us now focus our attention on the asymptotic minimax redundancy (1.2) of Clarke and Barron. If in (1.2) we again set d to 3, we obtain (1.9), which, numerically, is $\frac{3}{2} \log n - 1.96736 + o(1)$. Clarke and Barron prove that this minimax expression is only attained by the (classical) Jeffreys’ prior. In order to derive its quantum counterpart — at least, a restricted (to the family q_u) version — we have to determine the behavior of

$$\min_{-\infty < u < 1} \max_{0 \leq r \leq 1} S(\otimes^n \rho, \zeta_n(u)) \quad (3.2)$$

for $n \rightarrow \infty$. By Theorem 9 we know that for large n the relative entropy $S(\otimes^n \rho, \zeta_n(u))$ equals

$$\begin{aligned} \frac{3}{2} \log n - \frac{1}{2} - \frac{3}{2} \log 2 - (1 - u) \log(1 - r^2) + \frac{1}{2r} \log \left(\frac{1 - r}{1 + r} \right) \\ + \log \Gamma(1 - u) - \log \Gamma(5/2 - u), \end{aligned} \quad (3.3)$$

up to an error of the order $O(1/n)$, which is uniform in u and r as long as $0 \leq r \leq 1 - \varepsilon$ for any fixed $\varepsilon > 0$. Let us for the moment ignore the error term. Then what we have to do is to determine the minimax of the expression (3.3), that is

$$\frac{3}{2} \log n - \frac{1}{2} - \frac{3}{2} \log 2 + \min_{-\infty < u < 1} \max_{0 \leq r \leq 1} f(r, u), \quad (3.4)$$

where

$$f(r, u) = -(1 - u) \log(1 - r^2) + \frac{1}{2r} \log \left(\frac{1 - r}{1 + r} \right) + \log \Gamma(1 - u) - \log \Gamma(5/2 - u). \quad (3.5)$$

This is an easy task. First of all, if $u < .5$ then the function $f(r, u)$ is unbounded at $r = 1$. Hence, to determine the minimax, we can ignore that range of u . If $u = .5$, then $f(r, u)$ is maximal at $r = 1$, at which it attains the value $-\log 2 + \frac{1}{2} \log \pi \approx -0.120782$. On the other hand, if $u > .5$ then $f(r, u)$ attains a maximum in the interior of the interval $0 < r < 1$. To determine this maximum, we differentiate $f(r, u)$ with respect to r , to obtain

$$\frac{2r^2 - 1}{r(1 - r^2)} - \frac{2ru}{1 - r^2} - \frac{1}{2r^2} \log \left(\frac{1 - r}{1 + r} \right).$$

Equating this to 0 gives

$$u = 1 - \frac{1}{2r^2} - \frac{(1 - r^2)}{4r^3} \log \left(\frac{1 - r}{1 + r} \right). \quad (3.6)$$

Now we have to express r in terms of u , $r = r(u)$ say, substitute in $f(r, u)$, and determine $\min_{-\infty < u < 1} f(r(u), u)$. However, equivalently, we can express u in terms of r , $u = u(r)$ say (as was previously done in (3.6)), substitute in $f(r, u)$, and determine $\min_{0 \leq r \leq 1} f(r, u(r))$. In order to do so, we differentiate $f(r, u(r))$ with respect to r , equate the result to 0, and solve for r . Numerically, the result is $r \approx .961574$. Substituting this back into (3.6), we obtain $u \approx .542593$. The value of $f(r, u)$ at these values of r and u is -0.184320 . This is smaller than that previously found (-0.120782) for $u = .5$, so that particular value of u is not of concern for the minimax, as well.

In the beginning, we did ignore the error term. In fact, as is not very difficult to see, since the error term is uniform in u and r as long as $0 \leq r \leq 1 - \varepsilon$ for any fixed $\varepsilon > 0$, it is legitimate to ignore the error term. To be precise, the asymptotic minimax is the result above, subject to an error of $o(1)$, that is, the value of (3.3) for $r \approx .961574$ and $u \approx .542593$. This is $\frac{3}{2} \log n - 1.72404 + o(1)$. For $u = .5$, on the other hand, asymptotically, the maximum of the redundancy (2.31) (which, by the considerations above, is (3.3) for $r = 1$) equals $\frac{3}{2} \log n - \frac{1}{2} - \frac{5}{2} \log 2 + \frac{1}{2} \log \pi + o(1) \approx \frac{3}{2} \log n - 1.66050 + o(1)$. We must, therefore, conclude that — in contrast to the classical case [17, 18] — our trial candidate ($q_{0.5}$) for the quantum counterpart of Jeffreys' prior does not exactly achieve the minimax redundancy, although the prior $q_{0.542593}$ is remarkably close to $q_{0.5}$, the hypothesized “quantum Jeffreys' prior” from [52, 53].

We now concern ourselves with the asymptotic *maximin* redundancy. Clarke and Barron [17, 18] prove that the maximin redundancy is attained asymptotically, again, by the Jeffreys' prior. To derive the quantum counterpart of the maximin redundancy within our analytical framework, we would have to calculate

$$\max_w \min_{Q_n} \int_{x^2 + y^2 + z^2 \leq 1} S(\otimes^n \rho, Q_n) w(x, y, z) dx dy dz, \quad (3.7)$$

where Q_n varies over the $(2^{2n} - 1)$ -dimensional convex set of $2^n \times 2^n$ density matrices and w varies over all probability densities over the unit ball. As we already mentioned in the Introduction, in the classical case, due to a result of Aitchison [2, pp. 549/550], the minimum is achieved by setting Q_n to be the Bayes estimator, i.e., the average of all possible probability densities in the family that is considered with respect to the given probability distribution. In the quantum domain the same assertion is true. For the sake of completeness, we include the proof in the Appendix. We can, thus, take the quantum analog of the Bayes estimator to be the Bayesian density matrix $\zeta_n(u)$. That is, we set $Q_n = \zeta_n(u)$ in (3.7). Let us, for the moment, restrict the possible w 's over which the maximum is to be taken to the family q_u , $-\infty < u < 1$. Thus, we consider

$$\max_u \int_{x^2+y^2+z^2 \leq 1} S(\otimes^n \rho, \zeta_n(u)) q_u(x, y, z) dx dy dz. \quad (3.8)$$

By the definition (1.3) of relative entropy, we have

$$\begin{aligned} S(\otimes^n \rho, \zeta_n(u)) &= \text{Tr} \left(\otimes^n \rho \log \otimes^n \rho \right) - \text{Tr} \left(\otimes^n \rho \log \zeta_n(u) \right) \\ &= n \frac{(1-r)}{2} \log \frac{(1-r)}{2} + n \frac{(1+r)}{2} \log \frac{(1+r)}{2} - \text{Tr} \left(\otimes^n \rho \log \zeta_n(u) \right), \end{aligned}$$

the second line being due to (2.29). Therefore, we get

$$\begin{aligned} &\int_{x^2+y^2+z^2 \leq 1} S(\otimes^n \rho, \zeta_n(u)) q_u(x, y, z) dx dy dz \\ &= \left(n \int_0^1 \int_0^\pi \int_0^{2\pi} \left(\frac{(1-r)}{2} \log \frac{(1-r)}{2} + \frac{(1+r)}{2} \log \frac{(1+r)}{2} \right) r^2 q_u d\varphi d\vartheta dr \right. \\ &\quad \left. - \text{Tr} (\zeta_n(u) \log \zeta_n(u)) \right) \\ &= -n \left(\frac{-7+5u}{2(2-u)(1-u)} + \psi(5-2u) - \psi(1-u) \right) + S(\zeta_n(u)). \quad (3.9) \end{aligned}$$

From Theorem 10, we know the asymptotics of the von Neumann entropy $S(\zeta_n(u))$. Hence, we find that the expression (3.9) is asymptotically equal to

$$\begin{aligned} &\frac{3}{2} \log n + \left(-\frac{7}{2} + 2u \right) \log 2 \\ &\quad - \frac{14 - 20u + 7u^2}{2(2-u)(1-u)} + \log(\Gamma(1-u)) - \log(\Gamma(5/2-u)) \\ &\quad + (2-2u)(\psi(5-2u) - \psi(1-u)) + O\left(\frac{1}{n^{1-u}}\right). \quad (3.10) \end{aligned}$$

We have to, first, perform the maximization required in (3.8), and then determine the asymptotics of the result. Due to the form of the asymptotics in (3.10), we can, in fact, derive the proper result by proceeding in the reverse order. That is, we first determine the asymptotics of $\int S(\otimes^n \rho, \zeta_n(u)) q_u dx dy dz$, which we did in (3.10), and then we maximize the u -dependent part in (3.10) with respect to u (ignoring the error term). (In Figure 3 we display this u -dependent part over the range $[-0.2, 1]$.) Of course, we do the latter step by equating the first derivative of the u -dependent part in

(3.10) with respect to u to zero and solving for u . It turns out that this equation takes the appealingly simple form

$$2(1-u)^3(\psi'(1-u) - \psi'(5/2-u)) = 1. \quad (3.11)$$

Numerically, we find this equation to have the solution $u \approx .531267$, at which the asymptotic maximin redundancy assumes the value $\frac{3}{2} \log n - 1.77185 + O(1/n^{.468733})$. For $u = .5$, on the other hand, we have for the asymptotic redundancy (3.10), $\frac{3}{2} \log n - 2 - \frac{1}{2} \log 2 + \frac{1}{2} \log \pi + O(1/\sqrt{n}) \approx \frac{3}{2} \log n - 1.77421 + O(1/\sqrt{n})$. Again, we must, therefore, conclude that — in contrast to the classical case [17, 18] — our trial candidate ($q_{0.5}$) for the quantum counterpart of Jeffreys’ prior can not serve as a “reference prior,” in the sense introduced by Bernardo [9, 10]. Moreover, — again in contrast to the classical situation [28] — we find that the minimax and the maximin are *not* identical (although remarkably close). The two distinct priors yielding these values ($q_{0.542593}$, respectively $q_{0.531267}$) are themselves remarkably close, as well.

Figure 3

Since they are mixtures of product states, the matrices $\zeta_n(u)$ are classically — as opposed to EPR (Einstein–Podolsky–Rosen) — correlated [61]. Therefore, $S(\zeta_n(u))$ must not be less than the sum of the von Neumann entropies of any set of reduced density matrices obtained from it, through computation of partial traces. For positive integers, $n_1 + n_2 + \cdots = n$, the corresponding reduced density matrices are simply $\zeta_{n_1(u)}, \zeta_{n_2(u)}, \dots$, due to the mixing [6, Exercise 7.10]. Using these reduced density matrices, one can compute *conditional* density matrices and quantum entropies [13]. Clarke and Barron [17, p. 40] have an alternative expression for the redundancy in terms of conditional entropies, and it would be of interest to ascertain whether a quantum analogue of this expression exists.

Let us note that the theorem of Clarke and Barron utilized the uniform convergence property of the asymptotic expansion of the relative entropy (Kullback–Leibler divergence). Condition 2 in their paper [17] is, therefore, crucial. It assumes — as is typically the case classically — that the matrix of second derivatives, $J(\theta)$, of the relative entropy

is identical to the Fisher information matrix $I(\theta)$. In the quantum domain, however, in general, $J(\theta) \geq I(\theta)$, where $J(\theta)$ is the matrix of second derivatives of the quantum relative entropy (1.3) and $I(\theta)$ is the symmetric logarithmic derivative Fisher information matrix [42, 43]. The equality holds only for special cases. For instance, $J(\theta) > I(\theta)$ does hold if $r \neq 0$ for the situation considered in this paper. The volume element of the Kubo-Mori/Bogoliubov (monotone) metric [42, 43] is given by $\sqrt{\det J(\theta)}$. This can be normalized for the two-level quantum systems to be a member ($u = 1/2$) of a one-parameter family of probability densities

$$\frac{(1-u)\Gamma(5/2-u)r\log((1+r)/(1-r))\sin\vartheta}{\pi^{3/2}(3-2u)\Gamma(1-u)(1-r^2)^u}, \quad -\infty < u < 1, \quad (3.12)$$

and similarly studied, it is presumed, in the manner of the family q_u (cf. (1.7) and (2.5)) analyzed here. These two families can be seen to differ — up to the normalization factor — by the replacement of $\log((1+r)/(1-r))$ in (3.12) by, simply, r . (These two last expressions are, of course, equal for $r = 0$.) In general, the volume element of a monotone metric over the two-level quantum systems is of the form [42, eq. 3.17]

$$\frac{r^2 \sin \vartheta}{f((1-r)/(1+r))(1-r^2)^{1/2}(1+r)}, \quad (3.13)$$

where $f: \mathbb{R}^+ \rightarrow \mathbb{R}^+$ is an operator monotone function such that $f(1) = 1$ and $f(t) = tf(1/t)$. For $f(t) = (1+t)/2$, one recovers the volume element ($\sqrt{\det I(\theta)}$) of the metric of the symmetric logarithmic derivative, and for $f(t) = (t-1)/\log t$, that ($\sqrt{\det J(\theta)}$) of the Kubo-Mori/Bogoliubov metric [40, 42, 43]. (It would appear, then, that the only member of the family q_u proportional to a monotone metric is $q_{0.5}$, that is (1.6). The maximin result we have obtained above corresponding to $u \approx .531267$ — the solution of (3.11) — would appear unlikely, then, to extend globally beyond the family. Of course, a similar remark could be made in regard to the minimax, corresponding to $u \approx .542593$, as shown above.) While $J(\theta)$ can be generated from the relative entropy (1.3) (which is a limiting case of the α -entropies [41]), $I(\theta)$ is similarly obtained from [40, eq. 3.16]

$$\text{Tr } \rho_1 (\log \rho_1 - \log \rho_2)^2. \quad (3.14)$$

It might prove of interest to repeat the general line of analysis carried out in this paper, but with the use of (3.14) rather than (1.3). Also of importance might be an analysis in which the relative entropy (1.3) is retained, but the family (3.12) based on the Kubo-Mori/Bogoliubov metric is used instead of q_u . Let us also indicate that if one equates the asymptotic redundancy formula of Clarke and Barron (1.1) (using $w(\theta) = q_u(x, y, z)$) to that derived here (2.37), neglecting the residual terms, solves for $\det(I(\theta))$, and takes the square root of the result, one obtains a prior of the form (3.13) based on the monotone function $f(t) = t^{t/(t-1)}/e$. (Let us note that the reciprocal of the related “Morozova-Chentsov” function [42], $c(x, y) = 1/yf(x/y)$, in this case, is the *exponential* mean [44] of x and y , while for the minimal monotone metric, the reciprocal of the Morozova-Chentsov function is the *arithmetic* mean. It is, therefore, quite interesting from an information-theoretic point of view that these are, in fact, the only two means which furnish additive quasiarithmetic average codeword lengths [1, p. 157]. Also, it appears to be a quite important, challenging question — bearing upon the relationship between classical and quantum probability — to determine whether or

not a family of probability distributions over the Bloch sphere exists, which yields as its volume element for the corresponding Fisher information matrix, a prior of the form (3.13) with the noted $f(t) = t^{t/(t-1)}/e$.)

As we said in the Introduction, ideally we would like to start with a (suitably well-behaved) *arbitrary* probability density on the unit ball, determine the relative entropy of $\bigotimes^n \rho$ with respect to the average of $\bigotimes^n \rho$ over the probability density, then find its asymptotics, and finally, among all such probability densities, find the one(s) for which the minimax and maximin are attained. In this regard, we wish to mention that a suitable combination of results and computations from Sec. 2 with basic facts from representation theory of $SU(2)$ (cf. [58, 11] for more information on that topic) yields the following result.

Theorem 11. *Let w be a spherically symmetric probability density on the unit ball, i.e., $w = w(x, y, z)$ depends only on $r = \sqrt{x^2 + y^2 + z^2}$. Furthermore, let $\hat{\zeta}_n(w)$ be the average $\int_{x^2+y^2+z^2 \leq 1} (\bigotimes^n \rho) w dx dy dz$. Then the eigenvalues of $\hat{\zeta}_n(w)$ are*

$$\lambda_h = \frac{\pi}{2^{n-1}(n-2h+1)} \int_{-1}^1 r(1+r)^{n-h+1}(1-r)^h w(|r|) dr, \quad h = 0, 1, \dots, \left\lfloor \frac{n}{2} \right\rfloor, \quad (3.15)$$

with respective multiplicities

$$\frac{(n-2h+1)^2}{(n+1)} \binom{n+1}{h}, \quad (3.16)$$

and corresponding eigenspaces $\{v_{h,s}(P) : h \leq s \leq n-h, P \text{ a ballot path from } (0,0) \text{ to } (n, n-2h)\}$, which were described in Sec. 2.2.

The relative entropy of $\bigotimes^n \rho$ with respect to $\hat{\zeta}_n(w)$ is given by (2.31), with λ_h as given in (3.15).

We hope that this Theorem enables us to determine the asymptotics of the relative entropy and, eventually, to find, at least within the family of spherically symmetric (that is, unitarily-invariant) probability densities on the unit ball, the corresponding minimax and maximin redundancies. Doing so, would resolve the outstanding question of whether these two redundancies, in fact, coincide, as classical results would suggest [28].

4. SUMMARY

Clarke and Barron [17, 18] (cf. [45]) have derived several forms of asymptotic redundancy for arbitrarily parameterized families of probability distributions. We have been motivated to undertake this study by the possibility that their results may generalize, in some yet not fully understood fashion, to the quantum domain of noncommutative probability. (Thus, rather than probability densities, we have been concerned here with density matrices.) We have only, so far, been able to examine this possibility in a somewhat restricted manner. By this, we mean that we have limited our consideration to two-level quantum systems (rather than n -level ones, $n \geq 2$), and for the case $n = 2$, we have studied (what has proven to be) an analytically tractable one-parameter family of possible prior probability densities, q_u , $-\infty < u < 1$ (rather than the totality of

arbitrary probability densities). Consequently, our results can not be as definitive in nature as those of Clarke and Barron. Nevertheless, the analyses presented here reveal that our trial candidate ($q_{0.5}$, that is (1.6)) for the quantum counterpart of the Jeffreys' prior closely approximates those probability distributions which we have, in fact, found to yield the minimax ($q_{0.542593}$) and maximin ($q_{0.531267}$) for our one-parameter family (q_u).

Future research might be devoted to expanding the family of probability distributions used to generate the Bayesian density matrices for $n = 2$, as well as similarly studying the n -level quantum systems ($n > 2$). (In this regard, we have examined the situation in which $n = 2^m$, and the only $n \times n$ density matrices considered are simply the tensor products of m identical 2×2 density matrices. Surprisingly, for $m = 2, 3$, the associated trivariate candidate quantum Jeffreys' prior, taken, as throughout this study, to be proportional to the volume elements of the metrics of the symmetric logarithmic derivative (cf. [53]), have been found to be *improper* (nonnormalizable) over the Bloch sphere. The minimality of such metrics is guaranteed, however, only if "the whole state space of a spin is parameterized" [42].) In all such cases, it will be of interest to evaluate the characteristics of the relevant candidate quantum Jeffreys' prior *vis-à-vis* all other members of the family of probability distributions employed over the $(n^2 - 1)$ -dimensional convex set of $n \times n$ density matrices.

We have also conducted analyses parallel to those reported above, but having, *ab initio*, set either x or y to zero in the 2×2 density matrices (1.4). This, then, places us in the realm of real — as opposed to complex (standard or conventional) quantum mechanics. (Of course, setting *both* x and y to zero would return us to a strictly classical situation, in which the results of Clarke and Barron [17, 18], as applied to binomial distributions, would be directly applicable.) Though we have — on the basis of detailed computations — developed strong conjectures as to the nature of the associated results, we have not, at this stage of our investigation, yet succeeded in formally demonstrating their validity.

In conclusion, again in analogy to classical results, we would like to raise the possibility that the quantum asymptotic redundancies derived here might prove of value in deriving formulas for the *stochastic complexity* [45, 46] (cf. [55]) — the shortest description length — of a string of n *quantum* bits. The competing possible models for the data string might be taken to be the 2×2 density matrices (ρ) corresponding to different values of r , or equivalently, different values of the von Neumann entropy, $S(\rho)$.

APPENDIX: THE QUANTUM BAYES ESTIMATOR ACHIEVES THE MINIMUM AVERAGE ENTROPY

Let P_θ , $\theta \in \Theta$, be a family of density matrices, and let $w(\theta)$, $\theta \in \Theta$, be a probability density on Θ .

Theorem 12. *The minimum*

$$\min_Q \int w(\theta) S(P_\theta, Q) d\theta,$$

taken over all density matrices Q , is achieved by $M = \int w(\theta) P_\theta d\theta$.

PROOF. We look at the difference

$$\int w(\theta)S(P_\theta, Q) d\theta - \int w(\theta)S(P_\theta, M) d\theta,$$

and show that it is nonnegative. Indeed,

$$\begin{aligned} & \int w(\theta)S(P_\theta, Q) d\theta - \int w(\theta)S(P_\theta, M) d\theta \\ &= \int w(\theta) \operatorname{Tr}(P_\theta \log P_\theta - P_\theta \log Q) d\theta - \int w(\theta) \operatorname{Tr}(P_\theta \log P_\theta - P_\theta \log M) d\theta \\ &= \int w(\theta) \operatorname{Tr}(P_\theta (\log M - \log Q)) d\theta \\ &= \operatorname{Tr} \left(\left(\int w(\theta) P_\theta d\theta \right) (\log M - \log Q) \right) \\ &= \operatorname{Tr} (M (\log M - \log Q)) \\ &= S(M, Q) \geq 0, \end{aligned}$$

since relative entropies of density matrices are nonnegative [38, bottom of p. 17]. \square

ACKNOWLEDGMENTS

Christian Krattenthaler did part of this research at the Mathematical Sciences Research Institute, Berkeley, during the Combinatorics Program 1996/97. Paul Slater would like to express appreciation to the Institute for Theoretical Physics for computational support. This research was undertaken, in part, to respond to concerns (regarding the rationale for the presumed quantum Jeffreys' prior) conveyed to him by Walter Kohn and members of the informal seminar group he leads. The co-authors are grateful to: Ira Gessel for bringing them into initial contact *via* the Internet; to Helmut Prodinger and Peter Grabner for their hints regarding the asymptotic computations; to A. R. Bishop and an anonymous referee of [53]; and to the two anonymous referees of this paper itself, whose comments helped to considerably improve the presentation.
